Schultz W. Neuronal Reward and Decision Signals: From Theories to Data. *Physiol Rev* 95: 853–951, 2015. Published June 24, 2015; doi:10.1152/physrev.00023.2014.—Rewards are crucial objects that induce learning, approach behavior, choices, and emotions. Whereas emotions are difficult to investigate in animals, the learning function is mediated by neuronal reward prediction error signals which implement basic constructs of reinforcement learning theory. These signals are found in dopamine neurons, which emit a global reward signal to striatum and frontal cortex, and in specific neurons in striatum, amygdala, and frontal cortex projecting to select neuronal populations. The approach and choice functions involve subjective value, which is objectively assessed by behavioral choices eliciting internal, subjective reward preferences. Utility is the formal mathematical characterization of subjective value and a prime decision variable in economic choice theory. It is coded as utility prediction error by phasic dopamine responses. Utility can incorporate various influences, including risk, delay, effort, and social interaction. Appropriate for formal decision mechanisms, rewards are coded as object value, action value, difference value, and chosen value by specific neurons. Although all reward, reinforcement, and decision variables are theoretical constructs, their neuronal signals constitute measurable physical implementations and as such confirm the validity of these concepts. The neuronal reward signals provide guidance for behavior while constraining the free will to act.

I. INTRODUCTION

Rewards are the most crucial objects for life. Their function is to make us eat, drink, and mate. Species with brains that allow them to get better rewards will win in evolution. This is what our brain does, acquire rewards, and do it in the best possible way. It may well be the reason why brains have evolved. Brains allow multicellular organisms to move about the world. By displacing themselves they can access more rewards than happen to come along by chance, thus enhancing their chance of survival and reproduction. However, movement alone does not get them any food or mating partners. It is necessary to identify stimuli, objects, events, situations, and activities that lead to the best nutrients and mating partners. Brains make individuals learn, select, approach, and consume the best rewards for survival and reproduction and thus make them succeed in evolutionary selection. To do so, the brain needs to identify the reward value of objects for survival and reproduction, and then direct the acquisition of these reward objects through learning, approach, choices, and positive emotions. Sensory discrimination and control of movements serve this prime role of the brain. For these functions, nature has endowed us with explicit neuronal reward signals that process all crucial aspects of reward functions.

Rewards are not defined by their physical properties but by the behavioral reactions they induce. Therefore, we need behavioral theories that provide concepts of reward functions. The theoretical concepts can be used for making testable hypotheses for experiments and for interpreting the results. Thus the field of reward and decision-making is not only hypothesis driven but also concept driven. The field of reward and decision-making benefits from well-developed theories of behavior as the study of sensory systems benefits from signal detection theory and the study of the motor system benefits from an understanding of mechanics. Reward theories are particularly important because of the absence of specific sensory receptors for reward, which would have provided basic physical definitions. Thus the theories help to overcome the limited explanatory power of physical reward parameters and emphasize the requirement for behavioral assessment of the reward parameters studied. These theories make disparate data consistent and coherent and thus help to avoid seemingly intuitive but paradoxical explanations.

Theories of reward function employ a few basic, fundamental variables such as subjective reward value derived from measurable behavior. This variable condenses all crucial factors of reward function and allows quantitative formal-

0031-9333/15 Copyright © 2015 the American Physiological Society

ization that characterizes and predicts a large variety of behavior. Importantly, this variable is hypothetical and does not exist in the external physical world. However, it is implemented in the brain in various neuronal reward signals, and thus does seem to have a physical basis. Although sophisticated forms of reward and decision processes are far more fascinating than arcane fundamental variables, their investigation may be crucial for understanding reward processing. Where would we be without the discovery of the esoteric electron by J. J. Thompson 1897 in the Cambridge Cavendish Laboratory? Without this discovery, the microprocessor and the whole internet would be impossible. Or, if we did not know about electromagnetic waves, we might assume a newsreader sitting inside the radio while sipping our morning coffee. This review is particularly concerned with fundamental reward variables, first concerning learning and then related to decision-making.

The reviewed work concerns primarily neurophysiological studies on single neurons in monkeys whose sophisticated behavioral repertoire allows well detailed, quantitative behavioral assessments while controlling confounds from sensory processing, movements, and attention. Thus I am approaching reward processing from the point of view of the tip of a microelectrode, one neuron at a time, thousands of them over the years, in rhesus' brains with more than two billion neurons. I apologize to the authors whose work I have not been able to cite in full, as there is a large number of recent studies on the subject and I am selecting these studies by their contribution to the concepts being treated here.

II. REWARD FUNCTIONS

A. Proximal Reward Functions Are Defined by Behavior

We have sensory receptors that react to environmental events. The retina captures electromagnetic waves in a limited range. Optical physics, physical chemistry, and biochemistry help us to understand how the waves enter the eye, how the photons affect the ion channels in the retinal photoreceptors, and how the ganglion cells transmit the visual message to the brain. Thus sensory receptors define the functions of the visual system by translating the energy from environmental events into action potentials and sending them to the brain. The same holds for touch, pain, hearing, smell, and taste. If there are no receptors for particular environmental energies, we do not sense them. Humans do not feel magnetic fields, although some fish do. Thus physics and chemistry are a great help for defining and investigating the functions of sensory systems.

Rewards have none of that. Take rewarding stimuli and objects: we see them, feel them, taste them, smell them, or hear them. They affect our body through all sensory systems, but there is not a specific receptor that would capture the particular motivational properties of rewards. As reward functions cannot be explained by object properties alone, physics and chemistry are only of limited help, and we cannot investigate reward processing by looking at the properties of reward receptors. Instead, rewards are defined by the particular behavioral reactions they induce. Thus, to understand reward function, we need to study behavior. Behavior becomes the key tool for investigating reward function, just as a radio telescope is a key tool for astronomy.

The word reward has almost mystical connotations and is the subject of many philosophical treatises, from the ethics of the utilitarian philosophy of Jeremy Bentham (whose embalmed body is displayed in University College London) and John Stuart Mill to the contemporary philosophy of science of Tim Schroeder (39, 363, 514). More commonly, the man on the street views reward as a bonus for exceptional performance, like chocolate for a child getting good school marks, or as something that makes us happy. These descriptions are neither complete nor practical for scientific investigations. The field has settled on a number of well-defined reward functions that have allowed an amazing advance in knowledge on reward processing and have extended these investigations into economic decision-making. We are dealing with three, closely interwoven, functions of reward, namely, learning, approach behavior and decision-making, and pleasure.

1. Learning

Rewards have the potential to produce learning. Learning is Pavlov's main reward function (423). His dog salivates to a bell when a sausage often follows, but it does not salivate just when a bell rings without consequences. The animal's reaction to the initially neutral bell has changed because of the sausage. Now the bell predicts the sausage. No own action is required, as the sausage comes for free, and the learning happens also for free. Thus Pavlovian learning (classical conditioning) occurs automatically, without the subject's own active participation, other than being awake and mildly attentive. Then there is Thorndike's cat that runs around the cage and, among other things, presses a lever and suddenly gets some food (589). The food is great, and the cat presses again, and again, with increasing enthusiasm. The cat comes back for more. This is instrumental or operant learning. It requires an own action; otherwise, no reward will come and no learning will occur. Requiring an action is a major difference from Pavlovian learning. Thus operant learning is about actions, whereas Pavlovian learning is about stimuli. The two learning mechanisms can be distinguished schematically but occur frequently together and constitute the building blocks for behavioral reactions to rewards.

Rewards in operant conditioning are positive reinforcers. They increase and maintain the frequency and strength of the behavior that leads to them. The more reward Thorndike's cat gets, the more it will press the lever. Reinforcers do nt only strengthen and maintain behavior for the cat but also for obtaining stimuli, objects, events, activities, and situations as different as beer, whisky, alcohol, relaxation, beauty, mating, babies, social company, and hundreds of others. Operant behavior gives a good definition for rewards. Anything that makes an individual come back for more is a positive reinforcer and therefore a reward. Although it provides a good definition, positive reinforcement is only one of several reward functions.

2. Approach behavior and decision-making

Rewards are attractive. They are motivating and make us exert an effort. We want rewards; we do not usually remain neutral when we encounter them. Rewards induce approach behavior, also called appetitive or preparatory behavior, and consummatory behavior. We want to get closer when we encounter them, and we prepare to get them. We cannot get the meal, or a mating partner, if we do not approach them. Rewards usually do not come alone, and we often can choose between different rewards. We find some rewards more attractive than others and select the best reward. Thus we value rewards and then decide between them to get the best value. Then we consume them. So, rewards are attractive and elicit approach behavior that helps to consume the reward. Thus any stimulus, object, event, activity, or situation that has the potential to make us approach and consume it is by definition a reward.

3. Positive emotions

Rewards have the potential to elicit positive emotions. The foremost emotion evoked by rewards is pleasure. We enjoy having a good meal, watching an interesting movie, or meeting a lovely person. Pleasure constitutes a transient response that may lead to the longer lasting state of happiness. There are different degrees and forms of pleasure. Water is pleasant for a thirsty person, and food for a hungry one. The rewarding effects of taste are based on the pleasure it evokes. Winning in a big lottery is even more pleasant. But many enjoyments differ by more than a few degrees. The feeling of high that is experienced by sports people during running or swimming, the lust evoked by encountering a ready mating partner, a sexual orgasm, the euphoria reported by drug users, and the parental affection to babies constitute different forms (qualities) rather than degrees of pleasure (quantities).

Once we have experienced the pleasure from a reward, we may form a desire to obtain it again. When I am thirsty or hungry and know that water or food helps, I desire them. Different from such specific desire, there are also desires for imagined or even impossible rewards, such as flying to Mars, in which cases desires become wishes (514). Desire requires a prediction, or at least a representation, of reward and constitutes an active process that is intentional [in being about something (529)]. Desire makes behavior purposeful and directs it towards identifiable goals. Thus desire is the emotion that helps to actively direct behavior towards known rewards, whereas pleasure is the passive experience that derives from a received or anticipated reward. Desire has multiple relations to pleasure; it may be pleasant in itself (I feel a pleasant desire), and it may lead to pleasure (I desire to obtain a pleasant object). Thus pleasure and desire have distinctive characteristics but are closely intertwined. They constitute the most important positive emotions induced by rewards. They prioritize our conscious processing and thus constitute important components of behavioral control. These emotions are also called liking (for pleasure) and wanting (for desire) in addiction research (471) and strongly support the learning and approach generating functions of reward.

Despite their immense power in reward function, pleasure and desire are very difficult to assess in an objectively measurable manner, which is an even greater problem for scientific investigations on animals, despite attempts to anthropomorphize (44). We do not know exactly what other humans feel and desire, and we know even less what animals feel. We can infer pleasure from behavioral responses that are associated with verbal reports about pleasure in humans. We could measure blood pressure, heart rate, skin resistance, or pupil diameter as manifestations of pleasure or desire, but they occur with many different emotions and thus are unspecific. Some of the stimuli and events that are pleasurable in humans may not even evoke pleasure in animals but act instead through innate mechanisms. We simply do not know. Nevertheless, the invention of pleasure and desire by evolution had the huge advantage of allowing a large number of stimuli, objects, events, situations, and activities to be attractive. This mechanism importantly supports the primary reward functions in obtaining essential substances and mating partners.

4. Potential

Rewards have the potential to produce learning, approach, decisions, and positive emotions. They are rewards even if their functions are not evoked at a given moment. For example, operant learning occurs only if the subject makes the operant response, but the reward remains a reward even if the subject does not make the operant response and the reward cannot exert its learning function. Similarly an object that has the potential to induce approach or make me happy or desire it is a reward, without necessarily doing it every time because I am busy or have other reasons not to engage. Pavlovian conditioning of approach behavior, which occurs every time a reward is encountered as long as it evokes at least minimal attention, nicely shows this.

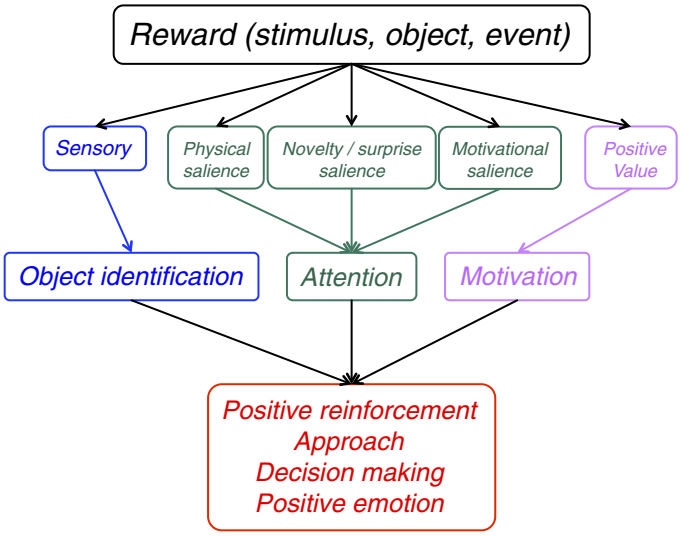

FIGURE 1. Reward components and their functions. The sensory component reflects the impact of environmental stimuli, objects, and events on the organism (blue). Pleasurable activities and situations belong also in this sensory component. The three salience components eliciting attentional responses (green) derive from the physical impact (*left*), novelty (*middle*), and commonly from reward and punishment (*right*). The specific positively motivating function of rewards derives from the value component (pink). Value does not primarily reflect physical parameters but the brain's subjective assessment of the usefulness of rewards for survival and reproduction. These reward components are either external (sensory, physical salience) or internal (generated by the brain; value, novelty/surprise salience, motivational salience). All five components together ensure adequate reward function.

5. Punishment

The second large category of motivating events besides rewards is punishment. Punishment produces negative Pavlovian learning and negative operant reinforcement, passive and active avoidance behavior and negative emotions like fear, disgust, sadness, and anger (143). Finer distinctions separate punishment (reduction of response strength, passive avoidance) from negative reinforcement (enhancing response strength, active avoidance).

6. Reward components

Rewarding stimuli, objects, events, situations, and activities consist of several major components. First, rewards have basic sensory components (visual, auditory, somatosensory, gustatory, and olfactory) (**FIGURE 1,** *left*), with physical parameters such as size, form, color, position, viscosity, acidity, and others. Food and liquid rewards contain chemical substances necessary for survival such as carbohydrates, proteins, fats, minerals, and vitamins, which contain physically measurable quantities of molecules. These sensory components act via specific sensory receptors on the brain. Some rewards consist of situations, which are detected by cognitive processes, or activities involving motor processes, which also constitute basic components analogous to sensory ones. Second, rewards are salient and thus elicit attention, which are manifested as orienting responses (**FIGURE 1,** *middle*). The salience of rewards derives from three principal factors, namely, their physical intensity and impact (physical salience), their novelty and surprise (novelty/surprise salience), and their general motivational impact shared with punishers (motivational salience). A separate form not included in this scheme, incentive salience, primarily addresses dopamine function in addiction and refers only to approach behavior (as opposed to learning) and thus to reward and not punishment (471). The term is at odds with current results on the role of dopamine in learning (see below) and reflects an earlier assumption of attentional dopamine function based on an initial phasic response component before distinct dopamine response components were recognized (see below). Third, rewards have a value component that determines the positively motivating effects of rewards and is not contained in, nor explained by, the sensory and attentional components (**FIGURE 1,** *right*). This component reflects behavioral preferences and thus is subjective and only partially determined by physical parameters. Only this component constitutes what we understand as a reward. It mediates the specific behavioral reinforcing, approach generating, and emotional effects of rewards that are crucial for the organism's survival and reproduction, whereas all other components are only supportive of these functions.

The major reward components together ensure maximal reward acquisition. Without the sensory component, reward discrimination would be difficult; without the attentional components, reward processing would be insufficiently prioritized; and without valuation, useless objects would be pursued. In practical reward experiments, the value component should be recognized as a distinct variable in the design and distinguished and uncorrelated from the sensory and attentional components.

The reward components can be divided into external components that reflect the impact of environmental stimuli, objects and events on the organism, and internal components generated by brain function. The sensory components are external, as they derive from external events and allow stimulus identification before evaluation can begin. In analogy, the external physical salience components lead to stimulus-driven attention. The foremost internal component is reward value. It is not inherently attached to stimuli, objects, events, situations, and activities but reflects the brain's assessment of their usefulness for survival and reproduction. Value cannot be properly defined by physical reward parameters but is represented in subjective preferences that are internal, private, unobservable, and incomparable between individuals. These preferences are elicited by approach behavior and choices that can be objectively measured. The internal nature of value extends to its associated motivational salience. Likewise, reward predictors are not

hardwired to outside events but require neuronal learning and memory processes, as does novelty/surprise salience which relies on comparisons with memorized events. Reward predictors generate top-down, cognitive attention that establishes a saliency map of the environment before the reward occurs. Further internal reward components are cognitive processes that identify potentially rewarding environmental situations, and motor processes mediating intrinsically rewarding movements.

B. Distal Reward Function Is Evolutionary Fitness

Modern biological theory conjectures that the currently existing organisms are the result of evolutionary competition. Advancing the idea about survival of the fittest organisms, Richard Dawkins stresses gene survival and propagation as the basic mechanism of life (114). Only genes that lead to the fittest phenotype will make it. The phenotype is selected based on behavior that maximizes gene propagation. To do so, the phenotype must survive and generate offspring, and be better at it than its competitors. Thus the ultimate, distal function of rewards is to increase evolutionary fitness by ensuring survival of the organism and reproduction. Then the behavioral reward functions of the present organisms are the result of evolutionary selection of phenotypes that maximize gene propagation. Learning, approach, economic decisions, and positive emotions are the proximal functions through which phenotypes obtain the necessary nutrients for survival, mating, and care for offspring.

Behavioral reward functions have evolved to help individuals to propagate their genes. Individuals need to live well and long enough to reproduce. They do so by ingesting the substances that make their bodies function properly. The substances are contained in solid and liquid forms, called foods and drinks. For this reason, foods and drinks are rewards. Additional rewards, including those used for economic exchanges, ensure sufficient food and drink supply. Mating and gene propagation is supported by powerful sexual attraction. Additional properties, like body form, enhance the chance to mate and nourish and defend offspring and are therefore rewards. Care for offspring until they can reproduce themselves helps gene propagation and is rewarding; otherwise, mating is useless. As any small edge will ultimately result in evolutionary advantage (112), additional reward mechanisms like novelty seeking and exploration widen the spectrum of available rewards and thus enhance the chance for survival, reproduction, and ultimate gene propagation. These functions may help us to obtain the benefits of distant rewards that are determined by our own interests and not immediately available in the environment. Thus the distal reward function in gene propagation and evolutionary fitness defines the proximal reward functions that we see in everyday behavior. That is why foods, drinks, mates, and offspring are rewarding.

The requirement for reward seeking has led to the evolution of genes that define brain structure and function. This is what the brain is made for: detecting, seeking, and learning about rewards in the environment by moving around, identifying stimuli, valuing them, and acquiring them through decisions and actions. The brain was not made for enjoying a great meal; it was made for getting the best food for survival, and one of the ways to do that is to make sure that people are attentive and appreciate what they are eating.

C. Types of Rewards

The term *reward* has many names. Psychologists call it positive reinforcer because it strengthens behaviors that lead to reward, or they call it outcome of behavior or goal of action. Economists call it a good or commodity and assess the subjective value for the decision maker as utility. We now like to identify the kinds of stimulus, object, event, activity, and situation that elicit the proximal functions of learning, approach, decision-making, and positive emotions and thus serve the ultimate, distal reward function of evolutionary fitness.

1. Primary homeostatic and reproductive rewards

To ensure gene propagation, the primary rewards mediate the survival of the individual gene carrier and her reproduction. These rewards are foods and liquids that contain the substances necessary for individual survival, and the activities necessary to mate, produce offspring, and care for the offspring. They are attractive and the main means to achieve evolutionary fitness in all animals and humans. Primary food and liquid rewards serve to correct homeostatic imbalances. They are the basis for Hull's drive reduction theory (242) that, however, would not apply to rewards that are not defined by homeostasis. Sexual behavior follows hormonal imbalances, at least in men, but is also strongly based on pleasure. To acquire and follow these primary alimentary and mating rewards is the main reason why the brain's reward system has evolved in the first place. Note that "primary" reward does not refer to the distinction between unconditioned versus conditioned reward; indeed, most primary rewards are learned and thus conditioned (foods are primary rewards that are typically learnt).

2. Nonprimary rewards

All other rewards serve to enhance the function of primary alimentary and mating rewards and thus enhance the chance for survival, reproduction, and evolutionary selection. Even though they are not homeostatic or reproductive rewards, they are rewards in their own rights. These nonprimary rewards can be physical, tangible objects like money, sleek cars, or expensive jewelry, or material liquids like a glass of wine, or particular ingredients like spices or alcohol. They can have particular pleasant sensory properties

like the visual features of a Japanese garden or a gorgeous sunset, the acoustic beauty of Keith Jarrett's Cologne Concert, the warm feeling of water in the Caribbean, the gorgeous taste of a gourmet dinner, or the irresistible odor of a perfume. Although we need sensory receptors to detect these rewards, their motivating or pleasing properties require further appreciation beyond the processing of sensory components **(FIGURE 1)**. A good example is Canaletto's Grand Canal **(FIGURE 2)** whose particular beauty is based on physical geometric properties, like the off-center Golden Ratio position reflecting a Fibonacci sequence (320). However, there is nothing intrinsically rewarding in this ratio of physical proportions. Its esthetic (and monetary) value is entirely determined by the subjective value assigned by our brain following the sensory processing and identification of asymmetry. Although we process great taste or smell as sensory events, we appreciate them as motivating and pleasing due to our subjective valuation. This rewarding function, cultivated in gourmet eating, enhances the appreciation and discrimination of high-quality and energy-rich primary foods and liquids and thus ultimately leads to better identification of higher quality food and thus higher survival chances (as gourmets are usually not lacking food, this may be an instinctive trait for evolutionary fitness). Sexual attraction is often associated with romantic love that, in contrast to straightforward sex, is not required for reproduction and therefore does not have primary reward functions. However, love induces attachment and facilitates care for offspring and thus supports gene propagation. Sexual rewards constitute also the most straightforward form of social rewards. Other social rewards include friendship, altruism, general social encounters, and societal activities that promote group coherence, cooperation, and competition which are mutually beneficial for group members and thus evolutionarily advantageous.

Nonphysical, nonmaterial rewards, such as novelty, gambling, jokes, suspense, poems, or relaxation, are attractive but less tangible than primary rewards. These rewards have no homeostatic basis and no nutrient value, and often do not promote reproduction directly. We may find the novelty of a country, the content of a joke, or the sequence of words in a poem more rewarding than the straightforward physical aspects of the country or the number of words in the joke or poem. But novelty seeking, and to some extent gambling, may help to encounter new food sources. Jokes, suspense, poems, and relaxation may induce changes of viewpoints and thus help to understand the world, which may help us to consider alternative food sources and mating partners, which is helpful when old sources dry up. Although these rewards act indirectly, they increase evolutionary fitness by enhancing the functions of primary alimentary and reproductive rewards.

Rewards can also be intrinsic to behavior (31, 546, 547). They contrast with extrinsic rewards that provide motivation for behavior and constitute the essence of operant behavior in laboratory tests. Intrinsic rewards are activities that are pleasurable on their own and are undertaken for their own sake, without being the means for getting extrinsic rewards. We may even generate our own rewards through internal decisions. Mice in the wild enter wheels and run on them on repeated occasions without receiving any other reward or benefit, like the proverbial wheel running hamster (358). Movements produce proprioceptive stimulation in muscle spindles and joint receptors, touch stimulation on the body surface, and visual stimulation from seeing the movement, all of which can be perceived as pleasurable and thus have reward functions. Intrinsic rewards are genuine rewards in their own right, as they induce learning, approach, and pleasure, like perfectioning, playing, and enjoying the piano. Although they can serve to condition higher order rewards, they are not conditioned, higher order rewards, as attaining their reward properties does not require pairing with an unconditioned reward. Other examples for intrinsic rewards are exploration, own beauty, gourmet eating, visiting art exhibitions, reading books, taking power and control of people, and investigating the natural order of the world. The pursuit of intrinsic rewards seems private to the individual but may inadver-

FIGURE 2. Subjective esthetic reward value derived from objective physical properties. The beauty of the Canaletto picture depends on the Golden Ratio of horizontal proportions, defined as $(a + b)/a = a/b \sim 0.618$; a and b for width of image. The importance of geometric asymmetry becomes evident when covering the left part of the image until the distant end of the canal becomes the center of the image: this increases image symmetry and visibly reduces beauty. However, there is no intrinsic reason why physical asymmetry would induce subjective value: the beauty appears only in the eye of the beholder. (Canaletto: The Upper Reaches of the Grand Canal in Venice, 1738; National Gallery, London.)

tently lead to primary and extrinsic rewards, like an explorer finding more food sources by venturing farther afield, a beauty queen instinctively promoting attractiveness of better gene carriers, a gourmet improving food quality through hightened culinary awareness, an artist or art collector stimulating the cognitive and emotional capacities of the population, a scholar providing public knowledge from teaching, a politician organizing beneficial cooperation, and a scientist generating medical treatment through research, all of which enhance the chance of survival and reproduction and are thus evolutionary beneficial. The double helix identified by Watson and Crick for purely scientific reasons is now beneficial for developing medications. The added advantage of intrinsic over solely extrinsic rewards is their lack of narrow focus on tangible results, which helps to develop a larger spectrum of skills that can be used for solving wider ranges of problems. Formal mathematical modeling confirms that systems incorporating intrinsic rewards outperform systems relying only on extrinsic rewards (546). Whereas extrinsic rewards such as food and liquids are immediately beneficial, intrinsic rewards are more likely to contribute to fitness only later. The fact that they have survived evolutionary selection suggests that their later benefits outweigh their immediate costs.

D. What Makes Rewards Rewarding?

Why do particular stimuli, objects, events, situations, and activities serve as rewards to produce learning, approach behavior, choices, and positive emotions? There are four separate functions and mechanisms that make rewards rewarding. However, these functions and mechanisms serve the common proximal and distal reward functions of survival and gene propagation. Individuals try to maximize one mechanism only to the extent that the other mechanisms are not compromised, suggesting that the functions and mechanisms are not separate but interdependent.

1. Homeostasis

The first and primary reward function derives from the need of the body to have particular substances for building its structure and maintaining its function. The concentration of these substances and their derivatives is finely regulated and results in homeostatic balance. Deviation from specific set points of this balance requires replenishment of the lost substances, which are contained in foods and liquids. The existence of hunger and thirst sensations demonstrates that individuals associate the absence of necessary substances with foods and liquids. We obviously know implicitly which environmental objects contain the necessary substances. When the blood sodium concentration exceeds its set point, we drink water, but depletion of sodium leads to ingestion of salt (472).

Two brain systems serve to maintain homeostasis. The hypothalamic feeding and drinking centers together with intestinal hormones deal with immediate homeostatic imbalances by rapidly regulating food and liquid intake (24, 46). In contrast, the reward centers mediate reinforcement for learning and provide advance information for economic decisions and thus are able to elicit behaviors for obtaining the necessary substances well before homeostatic imbalances and challenges arise. This preemptive function is evolutionarily beneficial as food and liquid may not always be available when an imbalance arises. Homeostatic imbalances are the likely source of hunger and thirst drives whose reduction is considered a prime factor for eating and drinking in drive reduction theories (242). They engage the hypothalamus for immediate alleviation of the imbalances and the reward systems for preventing them. The distinction in psychology between drive reduction for maintaining homeostasis and reward incentives for learning and pursuit may grossly correspond to the separation of neuronal control centers for homeostasis and reward. The neuroscientific knowledge about distinct hypothalamic and reward systems provides important information for psychological theories about homeostasis and reward.

The need for maintaining homeostatic balance explains the functions of primary rewards and constitutes the evolutionary origin of brain systems that value stimuli, objects, events, situations, and activities as rewards and mediate the learning, approach, and pleasure effects of food and liquid rewards. The function of all nonprimary rewards is built onto the original function related to homeostasis, even when it comes to the highest rewards.

2. Reproduction

In addition to acquiring substances, the other main primary reward function is to ensure gene propagation through sexual reproduction, which requires attraction to mating partners. Sexual activity depends partly on hormones, as shown by the increase of sexual drive with abstinence in human males. Many animals copulate only when their hormones put them in heat. Castration reduces sexual responses, and this deficit is alleviated by testosterone administration in male rats (146). Thus, as with feeding behavior, hormones support the reward functions involved in reproduction.

3. Pleasure

Pleasure is not only one of the three main reward functions but also provides a definition of reward. As homeostasis explains the functions of only a limited number of rewards, the prevailing reason why particular stimuli, objects, events, situations, and activities are rewarding may be pleasure. This applies first of all to sex (who would engage in the ridiculous gymnastics of reproductive activity if it were not for the pleasure) and to the primary homeostatic rewards of food and liquid, and extends to money, taste, beauty, social encounters and nonmaterial, internally set, and intrinsic

rewards. Pleasure as the main effect of rewards drives the prime reward functions of learning, approach behavior, and decision making and provides the basis for hedonic theories of reward function. We are attracted by most rewards, and exert excruciating efforts to obtain them, simply because they are enjoyable.

Pleasure is a passive reaction that derives from the experience or prediction of reward and may lead to a longer lasting state of happiness. Pleasure as hallmark of reward is sufficient for defining a reward, but it may not be necessary. A reward may generate positive learning and approach behavior simply because it contains substances that are essential for body function. When we are hungry we may eat bad and unpleasant meals. A monkey who receives hundreds of small drops of water every morning in the laboratory is unlikely to feel a rush of pleasure every time it gets the 0.1 ml. Nevertheless, with these precautions in mind, we may define any stimulus, object, event, activity, or situation that has the potential to produce pleasure as a reward.

Pleasure may add to the attraction provided by the nutrient value of rewards and make the object an even stronger reward, which is important for acquiring homeostatically important rewards. Once a homeostatic reward is experienced, pleasure may explain even better the attraction of rewards than homeostatis. Sensory stimuli are another good example. Although we employ arbitrary, motivationally neutral stimuli in the laboratory for conditioning, some stimuli are simply rewarding because they are pleasant to experience. The esthetic shape, color, texture, viscosity, taste, or smell of many rewards are pleasant and provide own reward value independently of the nutrients they contain (although innate and even conditioned mechanisms may also play a role, see below). Examples are changing visual images, movies, and sexual pictures for which monkeys are willing to exert effort and forego liquid reward (53, 124), and the ever increasing prices of paintings (fame and pride may contribute to their reward value). Not surprisingly, the first animal studies eliciting approach behavior by electrical brain stimulation interpreted their findings as discovery of the brain's pleasure centers (398), which were later partly associated with midbrain dopamine neurons (103, 155) despite the notorious difficulties of identifying emotions in animals.

4. Innate mechanisms

Innate mechanisms may explain the attractions of several types of reward in addition to homeostasis, hormones, and pleasure. A powerful example is parental affection that derives from instinctive attraction. Ensuring the survival of offspring is essential for gene propagation but involves efforts that are neither driven by homeostasis nor pleasure. As cute as babies are, repeatedly being woken up at night is not pleasurable. Generational attraction may work also in the other direction. Babies look more at human faces than at scrambled pictures of similar sensory intensity (610), which might be evolutionary beneficial. It focuses the baby's attention on particularly important stimuli, initially those coming from parents. Other examples are the sensory aspects of rewards that do not evoke pleasure, are nonnutritional, and are not conditioned but are nevertheless attractive. These may include the shapes, colors, textures, viscosities, tastes, or smells of many rewards (539), although some of them may turn out to be conditioned reinforcers upon closer inspection (640).

5. Punisher avoidance

The cessation of pain is often described as pleasurable. Successful passive or active avoidance of painful events can be rewarding. The termination or avoidance might be viewed as restoring a "homeostasis" of well being, but it is unrelated to proper vegetative homeostasis. Nor is avoidance genuine pleasure, as it is built on an adverse event or situation. The opponent process theory of motivation conceptualizes the reward function of avoidance (552), suggesting that avoidance may be a reward in its own right. Accordingly, the simple timing of a conditioned stimulus relative to an aversive event can turn punishment into reward (584).

E. Rewards Require Brain Function

1. Rewards require brains

Although organisms need sensory receptors to detect rewards, the impact on sensory receptors alone does not explain the effects of rewards on behavior. Nutrients, mating partners, and offspring are not attractive by themselves. Only the brain makes them so. The brain generates subjective preferences that reflect on specific environmental stimuli, objects, events, situations, and activities as rewards. These preferences are elicited by choices and quantifiable from behavioral reactions, typically choices but also reaction times and other measures. Reward function is explained by assuming the notion of value attributed to individual rewards. Value is not a physical property but determined by brain activity that interprets the potential effect of a reward on survival and reproduction. Thus rewards are internal to the brain and based entirely on brain function (547).

2. Explicit neuronal reward signals

Information processing systems work with signals. In brains, the signals that propagate through the circuits are the action potentials generated by each neuron. The output of the system is the observable behavior. In between are neurons and synapses that transmit and alter the signals. Each neuron works with thousands of messenger molecules and membrane channels that determine the action potentials. The number of action potentials, and somewhat their

pattern, varies monotonically with sensory stimulation, discrimination, and movements (3, 385). Thus the key substrates for the brain's function in reward are specific neuronal signals that occur in a limited number of brain structures, including midbrain dopamine neurons, striatum, amygdala, and orbitofrontal cortex **(FIGURE 3)**. Reward signals are also found in most component structures of the basal ganglia and the cerebral cortical areas, often in association with sensory or motor activity. The signals can be measured as action potentials by neurophysiology and are also reflected in transmitter concentrations assessed by electrochemistry (638) and as synaptic potentials detected by magnetic resonance imaging in blood oxygen level dependent (BOLD) signals (328). Whereas lesions in humans and animals demonstrate necessary involvements of specific brain structures in behavioral processes, they do not inform about the way the brain processes the information underlying these processes. Electric and optogenetic stimulation evokes action potentials and thus helps to dissect the influence of individual brain structures on behavior, but it does not replicate the natural signals that occur simultaneously in several interacting structures. Thus the investigation of neuronal signals is an important method for understanding crucial physiological mechanisms for the survival and reproduction of biological organisms.

3. Reward retina

Neuronal signals in sensory systems originate in specific receptors that define the signal content. However, rewards have no dedicated receptors. Neuronal processing would benefit from an explicit signal that identifies a reward irrespective of sensory properties and irrespective of actions required to obtain it. The signal might be analogous to visual responses of photoreceptors in the retina that constitute the first processing stage for visual perception. To obtain an explicit reward signal, the brain would extract the rewarding component from heterogeneous, polysensory environmental objects and events. A signal detecting the reward properties of an apple should not be concerned with its color unless color informs about reward properties of the fruit. Nor should it code the movement required to obtain the apple, other than assessing the involved effort as economic cost. External visual, somatic, auditory, olfactory, and gustatory stimuli predicting original, unconditioned rewards become conditioned rewards through Pavlovian conditioning. The issue for the brain is then to extract the reward information from the heterogeneous responses to the original and conditioned rewards and generate a common reward signal. Neurons carrying such a signal would constitute the first stage in the brain at which the reward property of environmental objects and events would be coded and conveyed to centers engaged in learning, approach, choice, and pleasure. Such abstract reward neurons would be analogous to the retinal photoreceptors as first visual processing stage (519).

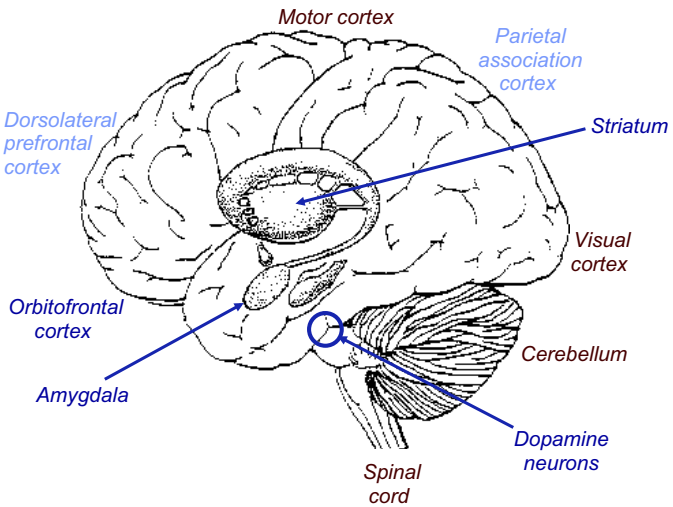

FIGURE 3. Principal brain structures for reward and decision-making. Dark blue: main structures containing various neuronal subpopulations coding reward without sensory stimulus or motor action parameters ("explicit reward signals"). Light blue: structures coding reward in conjunction with sensory stimulus or motor action parameters. Maroon: non-reward structures. Other brain structures with explicit or conjoint reward signals are omitted for clarity.

Despite the absence of specific reward receptors, there are chemical, thermal, and mechanical receptors in the brain, gut, and liver that detect important and characteristic reward ingredients and components, such as glucose, fatty acids, aromatic amino acids, osmolality, oxygen, carbon dioxide, temperature, and intestinal volume, filling, and contractions. In addition to these exteroceptors, hormone receptors are stimulated by feeding and sex (24, 46). These receptors are closest to being reward receptors but nevertheless detect only physical, sensory reward aspects, whereas reward value is still determined by internal brain activity.

The absence of dedicated receptors that by themselves signal reward value may not reflect evolutionary immaturity, as rewards are as old as multicellular organisms. Rather valuation separate from physical receptors may be an efficient way of coping with the great variety of objects that can serve as rewards at one moment or another, and of adapting reward value to changing requirements, including deprivation and satiation. Rather than having a complex, omnipotent, polysensory receptor that is sensitive to all possible primary and conditioned rewards and levels of deprivation, however infrequent they may occur, it might be easier to have a neuronal mechanism that extracts the reward information from the existing sensory receptors. The resulting neuronal reward signal would be able to detect rewarding properties in a maximum number of environmental objects, increase the harvest of even rare rewards, and relate their value to current body states, which all together enhance the chance of survival. Such a signal would be an efficient solution to the existential problem of benefitting from the

largest possible variety of rewards with reasonable hardware and energy cost.

III. LEARNING

A. Principles of Reward Learning

1. Advantage of learning

Learning is crucial for evolutionary fitness. It allows biological organisms to obtain a large variety of rewards in a wide range of environments without the burden of maintaining hard-wired mechanisms for every likely and unlikely situation. Organisms that can learn and adapt to their environments can live in more widely varying situations and thus acquire more foods and mating partners. Without learning, behavior for these many situations would need to be preprogrammed which would require larger brains with more energy demands. Thus learning saves brain size and energy and thus enhances evolutionary fitness. These advantages likely prompted the evolutionary selection of the learning function of rewards.

Learning processes lead to the selection of those behaviors that result in reward. A stimulus learned by Pavlovian conditioning elicits existing behavior when the stimulus is followed by reward. Natural behavioral reactions such as salivation or approach that improve reward acquisition become more frequent when a stimulus is followed by a reward. Male fish receiving a Pavlovian conditioned stimulus before a female approaches produce more offspring than unconditioned animals (223), thus demonstrating the evolutionary benefit of conditioning. Operant learning enhances the frequency of existing behavior when this results in reward. Thorndike's cat ran around randomly until it came upon a lever that opened a door to a food source. Then its behavior focused increasingly on the lever for the food. Thus Pavlovian and operant learning commonly lead to selection of behavior that is beneficial for survival.

Learning is instrumental for selecting the most beneficial behaviors that result in the best nutrients and mating partners in the competition for individual and gene survival. In this sense selection through learning is analogous to the evolutionary selection of the fittest genes. For both, the common principle is selection of the most efficient characteristics. The difference is on the order of time and scale. Selection of behavior through learning is based on outcome over minutes and hours, whereas selection of traits through evolution is based on survival of the individual. Evolutionary selection includes the susceptibility to reward and the related learning mechanisms that result in the most efficient acquisition of nutrients and mating partners.

2. Pavlovian learning

In Pavlov's experiment, the dog's salivation following the bell suggests that it anticipates the sausage. A Pavlovian conditioned visual stimulus would have a similar effect. The substances that individuals need to live are packaged in objects or liquids or are contained in animals they eat. We need to recognize a pineapple to get its juice that contains necessary substances like water, sugar, and fibers. Recognition of these packages could be hard wired into brain function, which would require a good number of neurons to detect a reasonable range of rewards. Alternatively, a flexible mechanism could dynamically condition stimuli and events with the necessary rewards and thus involve much less neurons representing the rewards. That mechanism makes individuals learn new packages when the environment changes. It also allows humans to manufacture new packages that were never encountered during evolution. Through Pavlovian conditioning humans learn the labels for hamburgers, baby food, and alcoholic beverages. Thus Pavlovian conditioning touches the essence of reward functions in behavior and allows individuals to detect a wide range of rewards from a large variety of stimuli while preventing run away neuron numbers and brain size. It is the simplest form of learning that increases evolutionary fitness and was thus selected by evolution.

Pavlovian conditioning makes an important conceptual point about reward function. We do not need to act to undergo Pavlovian conditioning. It happens without our own doing. But our behavior reveals that we have learned something, whether we wanted to or not. Pavlov's bell by itself would not make the dog salivate. But the dog salivates when it hears the bell that reliably precedes the sausage. From now on, it will always salivate to a bell, in particular when the bell occurs in the laboratory in which it has received all the sausages. Salivation is an automatic component of appetitive, vegetative approach behavior.

Although initially defined to elicit vegetative reactions, Pavlovian conditioning applies also to other behavioral reactions. The bell announcing the sausage elicits also approach behavior involving eye, limb, and licking movements. Thus Pavlovian learning concerns not only vegetative reactions but also skeletal movements. Furthermore, Pavlovian conditioning occurs in a large variety of behavioral situations. When operant learning increases actions that lead to reward, the more reward inadvertently conditions the involved stimuli in a Pavlovian manner. Thus Pavlovian and operant processes often go together in learning. When we move to get a reward, we also react to the Pavlovian conditioned, reward-predicting stimuli. In choices between different rewards, Pavlovian conditioned stimuli provide crucial information about the rewarded options. Thus Pavlovian and operant behavior constitute two closely linked forms of learning that extend well beyond laboratory experiments. Finally, Pavlovian conditioning concerns not

only the motivating components of rewards but also their attentional aspects. It confers motivational salience to arbitrary stimuli that elicits stimulus-driven attention and directs top-down attention to the reward and thus focuses behavior on pursuing and acquiring the reward. Taken together, Pavlovian conditioning constitutes a fundamental mechanism that is crucial for a large range of learning processes.

3. Reward prediction and information

Appetitive Pavlovian conditioning takes the past experience of rewards to form predictions and provide information about rewards. The bell in Pavlov's conditioning experiment has become a sausage predictor for the animal. By licking to the bell the dog demonstrates an expectation of the sausage that was evoked by the bell. Thus Pavlovian conditioning of the bell to the sausage has made the intrinsically neutral bell a reward predictor. The external stimulus or event (the bell) has become a predictor (of the sausage) and evokes an internal expectation (of the sausage) in the animal **(FIGURE 4)**. The same holds for any other reward predictor. The pineapple and the hamburger are predictors of the nutrients they contain.

Predictions tell us what is going to happen. This includes predictors of probabilistic rewards, even if the reward does not occur in every instance. Pavlov's bell predicts a sausage to the dog and at the same time induces salivation, licking, and approach. Thus Pavlovian conditioning confers two components, a predictive and an incentive property. The predictive component indicates what is going to happen now. The incentive property induces action, such as salivation, licking, and approach, which help to obtain and ingest the sausage. The two properties are separated in time in the classic and widely used delayed response tasks in which initial instructive stimuli have reward-predicting properties without eliciting a reward-directed action (but ocular saccades), whereas the final trigger or releasing stimulus induces the behavioral action and thus has both predictive and incentive properties. The predictive and incentive properties are separated spatially with different stimulus and goal (lever) positions and are dissociable in the behavior of particular rat strains. Specially bred sign-tracking rats approach the conditioned predictive stimulus, whereas goal trackers go directly to the reward upon stimulus appearance, indicating separation of predictive and incentive properties in goal trackers (163).

The predictive component can be further distinguished from an informational component. Once a stimulus has been Pavlovian conditioned, it confers information about the reward. The information does not necessarily predict explicitly what is actually going to happen every time, not even probabilistically. Through Pavlovian conditioning I have learned that a particular sign on a building indicates a pub because I have experienced the beer inside. The atmosphere and the beer represent a value to me that is assigned in a Pavlovian manner to the pub sign. I can pass the pub sign without entering the pub, however difficult that may be. Thus the sign is informational but does not truly predict a pint, only its potential, nor does it have the incentive properties at that moment to make me go in and get one. Then I may run into an unknown pub and experience a different beer, and I undergo another round of Pavlovian conditioning to the value of that particular pub sign. When I need to choose between different pubs, I use the information about their values rather than explicit predictions of getting a beer in every one of them. Thus Pavlovian conditioning sets up predictions that contain reward information. The predictions indicate that a reward is going to occur this time, whereas the reward informations do not necessarily result in reward every time.

The distinction between explicit prediction and information is important for theories of competitive decision-making. Value information about a reward is captured in the term of action value in machine learning, which indicates the value resulting from a particular action, without requiring to actually choosing it and obtaining that value (575). In analogy, object value indicates the value of a reward object irrespective of choosing and obtaining it. Individuals make decisions by comparing the values between the different actions or objects available and then selecting only the action or object with the highest value (see below **FIGURE 36*C***). Thus the decision is based on the information about

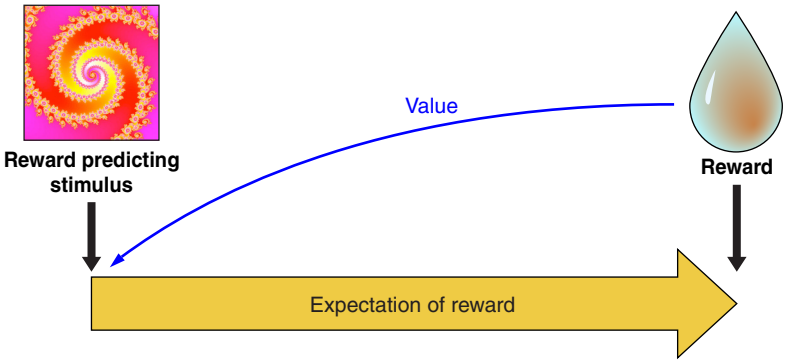

FIGURE 4. Pavlovian reward prediction. With conditioning, an arbitrary stimulus becomes a reward predictor and elicits an internal expectation of reward. Some of the behavioral reactions typical for reward occur also after the stimulus (Pavlovian stimulus substitution), in particular approach behavior, indicating that the stimulus has acquired reward value (blue arrow).

each reward value and not on the explicit prediction that every one of these rewards will be actually experienced, as only the chosen reward will occur. In this way, Pavlovian conditioning is a crucial building block for reward information in economic decisions. Separate from the decision mechanism, the acquisition and updating of action values and object values requires actual experience or predictions derived from models of the world, which is captured by model free and model-based reinforcement learning, respectively. Other ways to establish reward predictions and informations involve observational learning, instructions, and deliberate reflections that require more elaborate cognitive processes. All of these forms produce reward information that allows informed, competitive choices between rewards.

4. Pavlovian learning produces higher order rewards

Reward-predicting stimuli established through Pavlovian conditioning become higher order, conditioned rewards. By itself a red apple is an object without any intrinsic meaning. However, after having experienced its nutritious and pleasantly tasting contents, the apple with its shape and color has become a reinforcer in its own right. As a higher order, conditioned reward, the apple serves all the defining functions of rewards, namely, learning, approach behavior, and pleasure. The apple serves as a reinforcer for learning to find the vendor's market stand. When we see the apple, we approach it if we have enough appetite. We even approach the market stand after the apple has done its learning job. And seeing the delicious apple evokes a pleasant feeling. The apple serves these functions irrespective of explicitly predicting the imminent reception of its content or simply informing about its content without being selected. Thus Pavlovian conditioning labels arbitrary stimuli and events as higher order rewards that elicit all reward functions. All this happens without any physical change in the apple. The only change is in the eye of the beholder, which we infer from behavioral reaction.

The notion that Pavlovian conditioning confers higher order reward properties to arbitrary stimuli and events allows us to address a basic question. Where in the body is the original, unconditioned effect of rewarding substances located (517, 640)? The functions of alimentary rewards derive from their effects on homeostatic mechanisms involved in building and maintaining body structure and function. In the case of an apple, the effect might be an increase in blood sugar concentration. As this effect would be difficult to perceive, the attraction of an apple might derive from various stimuli conditioned to the sugar increase, such vision of the apple, taste, or other conditioned stimuli. Mice with knocked out sweet taste receptors can learn, approach, and choose sucrose (118), suggesting that the calories and the resulting blood sugar increase constitute the unconditioned reward effect instead of or in addition to taste. Besides being an unconditioned reward (by evoking pleasure or via innate mechanisms, see above), taste may also be a conditioned reward, similar to the sensory properties of other alimentary rewards, including temperature (a glass of unpleasant, luke warm water predicting reduced plasma osmolality) and viscosity (a boring chocolate drink predicting calories). These sensations guide ingestion that will ultimately lead to the primary reward effect. However, the conditioned properties are only rewarding as long as the original, unconditioned reward actually occurs. Diets lacking just a single essential amino acid lose their reward functions within a few hours or days and food aversion sets in (181, 239, 480). The essential amino acids are detected by chemosensitive neurons in olfactory cortex (314), suggesting a location for the original effects of amino acids with rewarding functions. Thus the better discernible higher order rewards facilitate the function of primary rewards that have much slower and poorly perceptible vegetative effects.

A similar argument can be made for rewards that do not address homeostasis but are based on the pleasure they evoke. The capacity of some unconditioned rewards to evoke pleasure and similar positive emotions is entirely determined by brain physiology. Pleasure as an unconditioned reward can serve to produce higher order, conditioned rewards that are also pleasurable. A good example are sexual stimuli, like body parts, that have unconditioned, innate reward functions and serve to make intrinsically neutral stimuli, like signs for particular stores or bars, predictors of sexual events and activity.

Taken together, the primary, homeostatic, or pleasurable reward functions are innate and determined by the physiology of the body and its brain that emerged from evolutionary selection. Individuals without such brains or with brains not sensing the necessary rewards have conceivably perished in evolution. The primary rewards come in various forms and "packages" depending on the environment in which individuals live. The same glucose molecule is packaged in sugar beets or bananas in different parts of the world. Conditioning through the actual experience within a given environment facilitates the detection of the primary rewards. Thus, in producing higher order rewards, Pavlovian learning allows individuals to acquire and optimally select homeostatic and pleasurable rewards whose primary actions may be distant and often difficult to detect.

5. Operant learning

Getting rewards for free sounds like paradise. But after Adam took Eve's apple, free rewards became more rare, and Pavlovian learning lost its exclusiveness. We often have to do something to get rewards. Learning starts with a reward that seems to come out of nowhere but actually came from an action, and we have to try and figure out what made it appear. The rat presses a lever by chance and receives a drop of sugar solution. The sugar is great, and it presses again, and again. It comes back for more. The frequency of its

behavior that results in the sugar increases. This is positive reinforcement, the more reward the animal gets the more it acts, the essence of Thorndike's Law of Effect (589). Crucial for operant learning is that the animal learns about getting the sugar drop only by pressing the lever. Without lever pressing it would not get any sugar, and the behavior would not get reinforced. If the sugar comes also without lever pressing, the sugar does not depend on lever pressing, and the rat would not learn to operate the lever (but it might learn in a Pavlovian manner that the experimental box predicts sugar drops).

Operant reinforcement means that we act more when we get more from the action. However, due to the somewhat voluntary nature of the action involved, the inverse works also. The more we act, the more we get. Our behavior determines how much we get. We get something for an action, which is the bonus or effort function of reward. We can achieve something by acting. We have control over what we get. Knowing this can motivate us. Operant learning allows behavior to become directed at a rewarding goal. We act to obtain a reward. Behavior becomes causal for obtaining reward. Thus operant learning represents a mechanism by which we act on the world to obtain more rewards. Coconuts drop only occasionally from the tree next to us. But we can shake the tree or sample other trees, not just because the coconut reinforced this behavior but also because we have the goal to get more coconuts. In eliciting goal-directed action, operant learning increases our possibilities to obtain the rewards we need and thus enhances our chance for survival and reproduction.

6. Value updating, goal-directed behavior, and habits

Value informations for choices need to be updated when reward conditions change. For example, food consumption increases the specific satiety for the consumed reward and thus decreases its subjective value while it is being consumed. In addition, the general satiety evolving in parallel lowers the reward value of all other foods. Although the values of all rewards ever encountered could be continuously updated, it would take less processing and be more efficient to update reward values only at the time when the rewards are actually encountered and contribute to choices. Reward values that are computed relative to other options should be updated when the value of any of the other option changes.

Operant learning directs our behavior towards known outcomes. In goal-directed behavior, the outcome is represented during the behavior leading to the outcome, and furthermore, the contingency of that outcome on the action is represented (133). In contrast, habits arise through repeated performance of instrumental actions in a stereotyped fashion. Habits are not learned with a new task from its outset but form gradually after an initial declarative, goal-directed learning phase (habit formation rather than habit learning). They are characterized by stimulus-response (S-R) performance that becomes "stamped-in" by reinforcement and leads to inflexible behavior. Despite their automaticity, habits extinguish with reinforcer omission, as do other forms of behavior. In permitting relatively automatic performance of routine tasks, habits free our attention, and thus our brains, for other tasks. They are efficient ways of dealing with repeated situations and thus are evolutionary beneficial.

Value updating differs between goal-directed behavior, Pavlovian predictions, and habits (133). Specific tests include devaluation of outcomes by satiation that reduces subjective reward value (133). In goal-directed behavior, such satiation reduces the operant response the next time the action is performed. Crucially, the effect occurs without pairing the action with the devalued outcome, which would be conventional extinction. The devaluation has affected the representation of the outcome that is being accessed during the action. In contrast, habits continue at unreduced magnitude until the devalued outcome is experienced after the action, at which point conventional extinction occurs. Thus, with habits, values are only retrieved from memory and updated at the time of behavior. Devaluation without action-outcome pairing is a sensitive test for distinguishing goal-directed behavior from habits and is increasingly used in neuroscience (133, 399, 646). Like goal-directed behavior, Pavlovian values can be sensitive to devaluation via representations and update similarly without repairing, convenient for rapid economic choices (however, Pavlovian conditioning is not goal "directed" as it does not require actions). Correspondingly, reward neurons in the ventral pallidum start responding to salt solutions when they become rewarding following salt depletion, even before actually experiencing the salt in the new depletion state (591). In conclusion, whether updating is immediate in goal-directed behavior or gradually with habit experience, values are only computed and updated at the time of behavior.

B. Neuronal Signals for Reward Learning

1. Basic conditions of learning: contiguity and contingency

In both Pavlovian and operant conditioning, an event (stimulus or action) is paired in time, and often in location, with a reinforcer to produce learning. In delay conditioning, the stimulus or action lasts until the reinforcer occurs. In trace conditioning, which is often less effective (47, 423), the stimulus or action terminates well before the reinforcer. Trace conditioning, but not delay conditioning, with aversive outcomes is disrupted by lesions of the hippocampus (47, 356, 553), although presenting the stimulus briefly again with the outcome restores trace conditioning (27). Thus temporal contiguity is important for conditioning.

What Pavlov did not know was that stimulus-reward pairing was not sufficient for conditioning. Rescorla showed in his "truly random" experiment that the key variable underlying conditioning is the difference in outcome between the presence and absence of a stimulus (or action) (459). Conditioning occurs only when reinforcement is dependent or "contingent" on the stimulus (or an action), and this condition applies also to rewards (126). When the same reward occurs also without the stimulus, the stimulus is still paired with reward but carries no specific reward information, and no conditioning occurs. Thus contingency refers to the intuitive notion that we learn only something that carries specific information or that decreases the uncertainty in the environment (reduction of informational entropy). Contingency is usually defined as difference in reinforcement between stimulus (or action) presence and background (stimulus absence) (**FIGURE 5*A***). A positive difference produces excitatory conditioning (positive learning, left of diagonal), whereas a negative difference produces inhibitory conditioning (negative learning, right of diagonal). Zero contingency produces no conditioning (diagonal line) (but likely perceptual learning). Backward conditioning (reward before stimulus) is ineffective or even produces inhibitory conditioning because the reward occurs without relation to the stimulus. Timing theories of conditioning define contingency as stimulus-to-intertrial ratio of reinforcement rates (175). More frequent reward during the stimulus compared with the no-stimulus intertrial interval makes the reward more contingent on the stimulus. When the same reward occurs later after stimulus onset (temporal discounting), stimulus-to-intertrial reward ratio decreases and thus lowers contingency, although other explanations are also valid (see below). Thus, after contiguity and stimulus-outcome pairing, contingency is the crucial process in conditioning. It determines reward predictions and informations, which are crucial for efficient decisions, and it produces higher order rewards, which drive most of our approach behavior.

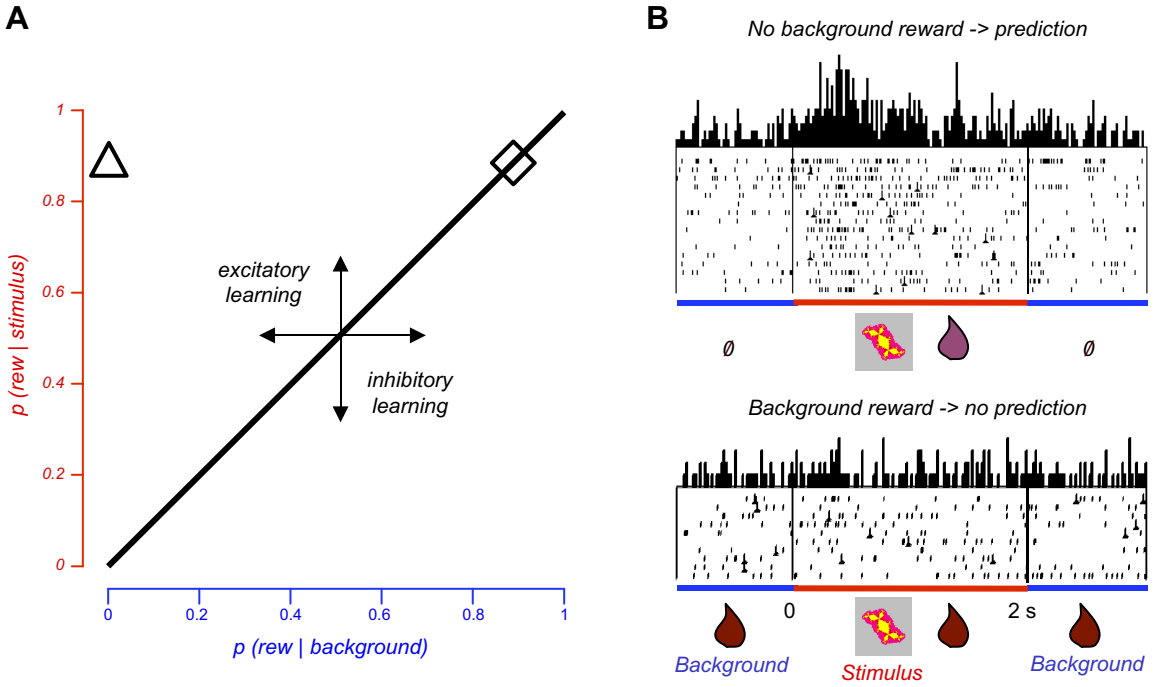

FIGURE 5. Reward contingency. *A:* role of contingency in learning. Contingency is shown as reward difference between stimulus presence and absence (background). Abscissa and ordinate indicate conditional reward probabilities. Higher reward probability in the presence of the stimulus compared with its absence (background) induces positive conditioning (positive contingency, triangle). No learning occurs with equal reward probabilities between stimulus and background (diagonal line, rhombus). Reward contingency applies to Pavlovian conditioning (shown here; reward contingent on stimulus) and operant conditioning (reward contingent on action). [Graph inspired by Dickinson (132).] *B:* contingency-dependent response in single monkey amygdala neuron. *Top*: neuronal response to conditioned stimulus (reward $P = 0.9$; red) set against low background reward probability ($P = 0.0$; blue) (triangle in *A*). *Bottom*: lack of response to same stimulus paired with same reward ($P = 0.9$) when background produces same reward probability ($P = 0.9$) (rhombus in *A*) which sets reward contingency to 0 and renders the stimulus uninformative. Thus the neuronal response to the reward-predicting stimulus depends entirely on the background reward and thus reflects reward contingency rather than stimulus-reward pairing. A similar drop in neuronal responses occurs with comparable variation in reward magnitude instead of probability (41). Perievent time histograms of neuronal impulses are shown above raster displays in which each dot denotes the time of a neuronal impulse relative to a reference event (stimulus onset, time = 0, vertical line at left; line to right indicates stimulus offset). [From Bermudez and Schultz (41).]

2. Neuronal contingency tests

Standard neuronal learning and reversal studies test contiguity by differentially pairing stimuli (or actions) with reward. Although they sometimes claim contingency testing, the proper assessment of contingency requires the distinction against contiguity of stimulus-reward pairing. As suggested by the "truly random" procedure (459), the distinction can be achieved by manipulating reward in the absence of the stimulus (or action).

A group of amygdala neurons respond to stimuli predicting more frequent or larger rewards compared with background without stimuli (**FIGURE 5*B***, *top*). These are typical responses to reward-predicting stimuli seen for 30 years in all reward structures. However, many of these neurons lose their response in a contingency test in which the same reward occurs also during the background without stimuli, even though stimulus, reward during stimulus and stimulus-reward pairing are unchanged (41) (**FIGURE 5*B***, *bottom*). Thus the responses do not just reflect stimulus-reward pairing but depend also on positive reward contingency, requiring more reward during stimulus presence than absence (however, amygdala neurons are insensitive to negative contingency). Although the stimulus is still paired with the reward, it loses its specific reward information and prediction; the amygdala responses reflect that lost prediction. Correspondingly, in an operant test, animals with amygdala lesions fail to take rewards without action into account and continue to respond after contingency degradation (399), thus showing an important role of amygdala in coding reward contingency.

Reward contingency affects also dopamine responses to conditioned stimuli. In an experiment designed primarily for blocking (see below **FIGURE 8*A***), a phasic environmental stimulus constitutes the background, and the crucial background test varies the reward with that environmental stimulus. Dopamine neurons are activated by a specific rewarded stimulus in the presence of an unrewarded environmental stimulus (positive contingency) but lose the activation in the presence of a rewarded environmental stimulus (zero contingency) (618). The stimulus has no specific information and prediction when the environmental stimulus already fully predicts the reward. Another experiment shows that these contingency-dependent dopamine responses may be important for learning. Using optogenetic, "rewarding" stimulation of dopamine neurons, behavioral responses (nose pokes) are only learned when the stimulation was contingent on the nose pokes, whereas contingency degradation by unpaired, pseudorandom stimulation during nose pokes and background induces extinction [truly random control with altered p(stimulation|nose poke)] (641).

Taken together, amygdala and dopamine neurons take the reward in the absence of the stimulus into account and thus are sensitive to contingency rather than simple stimulus-reward pairing. They fulfill the crucial requirement for coding effective reward information and prediction and thus may provide crucial inputs to neuronal decision mechanisms. Also, these neuronal signals demonstrate a physical basis for the theoretical concept of contingency and thus strengthen the plausibility of the most basic assumption of animal learning theory.

3. Prediction error learning theory

Contingency, in addition to stimulus-reward pairing (contiguity), is necessary for rewards to induce conditioning. Reward is contingent on a stimulus only when it differs between stimulus presence and absence. When reward is identical, including its time of occurrence, between stimulus presence and absence, it is already predicted by the objects that exist during stimulus presence and absence and therefore not surprising. Hence, the stimulus will not be learned.

The formal treatment of surprise in conditioning employs the concept of prediction error. A reward prediction error PE is the difference between received reward λ and reward prediction V in trial t

$$\mathrm{PE}(t) = \lambda(t) - \mathrm{V}(t) \qquad (1)$$

This formal definition of "error" extends beyond the colloquial meaning of inaccurate behavior. Prediction errors occur whenever *Equation 1* applies, irrespective of whether they simply occur during behavioral learning or are actually being used for learning.

Animal learning theory aims to explain the role of contingency in conditioning by formalizing how prediction errors update reward predictions from previously experienced rewards (460). The new prediction V for trial $t+1$ derives from the current prediction V(t) and the prediction error PE(t) weighted by learning rate α

$$\mathrm{V}(t+1) = \mathrm{V}(t) + \alpha * \mathrm{PE}(t) \qquad (2)$$

Note that V captures the sum of predictions if several stimuli are present. According to this account, conditioning constitutes error driven learning **(FIGURE 6*A*)**. When the outcome differs from the prediction, a prediction error proportional to that difference is generated and added to the current prediction after weighting by learning rate α. When α is set to 1.0, the new prediction is updated in one trial. However, learning rates are usually <1.0, which leads to the typical asymptotic learning curves during which prediction errors decline gradually **(FIGURE 6*B*)**.

Rewards that are better than predicted generate positive prediction errors and lead to response acquisition, whereas worse rewards generate negative prediction errors and lead to extinction of behavior. When the prediction error becomes zero, no further learning occurs and the prediction

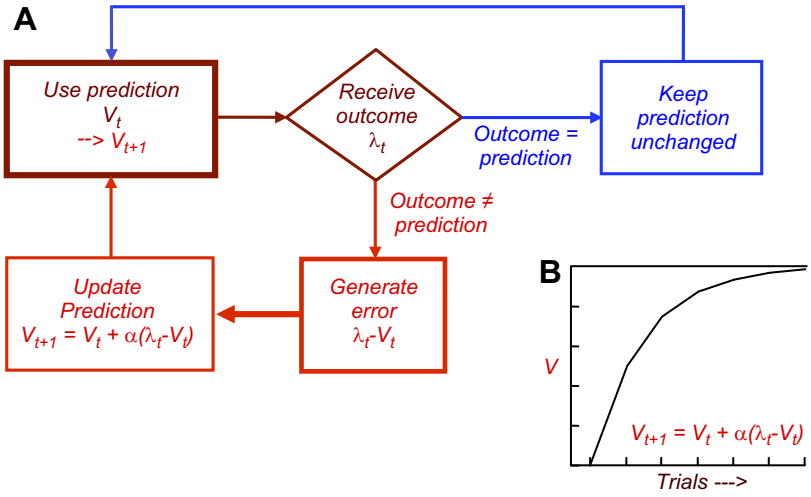

FIGURE 6. Learning with prediction errors. *A:* feedback circuit diagram for prediction updating by error. An error is generated when outcome (reward, punisher) differs from its prediction. In Pavlovian conditioning, a prediction error after an outcome change leads to prediction updating which leads to a behavioral change. In operant conditioning, a prediction error after an outcome change leads to a behavioral change which leads to prediction updating. In contrast, no prediction error is generated when the outcome matches the prediction, and behavior remains unchanged. V is reward prediction, λ is reward, α is learning rate, and *t* is trial. *B:* typical learning curve, generated by gradually declining prediction errors [λ(*t*) − V(*t*)].

remains stable. Thus learning advances only to the extent to which a reward is unpredicted and slows progressively with increasingly accurate predictions. This formalism views learning intuitively as a change in behavior that occurs when encountering something new or different than predicted, whereas behavior stays the same when everything occurs according to "plan."

Positive prediction errors direct organisms to maximal rewards, whereas negative prediction errors direct them away from poor outcomes. Obviously, individuals appreciate positive prediction errors and hate negative ones. Optimal behavior for maximizing rewards is characterized by many positive prediction errors and few negative ones.

Contingency is based on prediction errors. Contingency is non-zero, and prediction errors are elicited, when reward differs between stimulus presence and absence. This is the crucial requirement for learning. When reward is identical during stimulus presence and absence, there is no contingency, no prediction error, and no learning.

Specific learning situations benefit from extensions of the basic Rescorla-Wagner rule. Attentional learning rules relate the capacity to learn (associability) to the degree of attention evoked by the stimulus, which depends on degree of surprise (prediction error) experienced in the recent past (prediction error in the current trial cannot contribute to attention to the stimulus, as the error occurs only after the stimulus). Learning rate α is modified according to the weighted unsigned (absolute) prediction error in the recent past (425)

$$\alpha = \kappa \left| \lambda(t) - V(t) \right| \qquad (3)$$

with κ as weighting parameter. Thus learning rate increases with large prediction errors, as in the beginning of learning or with large step changes, resulting in strong influences of prediction error and thus fast learning according to *Equation 2*. In contrast, learning slows with small prediction errors from small changes.

When rewards are drawn from different probability distributions, comparable learning can be achieved by scaling the update component α*PE to the standard deviation σ of the respective reward distribution by either (438)

$$\alpha^{\circ} = \alpha / \sigma \qquad (3A)$$

or

$$PE(t)^{\circ} = PE(t) / \sigma \qquad (3B)$$

Behavioral tests with measurable prediction errors demonstrate that scaling learning rate α (*Equation 3A*) by standard deviation may produce constant learning rates with probability distributions differing only in standard deviation (384), which can be formulated as

$$\alpha = \kappa / \sigma \left| \lambda(t) - V(t) \right| \qquad (3C)$$

Thus risk may affect learning in two separate ways, by increasing learning rate α via the attentional effect of the prediction error (*Equation 3*), and by decreasing learning rate or prediction error via division by standard deviation σ (*Equations 3A* and *3B*).

The Rescorla-Wagner learning rule models Pavlovian conditioning: changes in outcome lead to prediction errors that lead to changes in prediction and consequently changes in behavior. The learning rule extends to operant conditioning: changes in outcome produce prediction errors that lead to behavioral changes which then result in changes in prediction.

In realistic situations, rewards may be unstable, which results in frequent prediction errors, continuous updating of predictions, and correspondingly varying behavior. Thus learning of a single, stable reward is a special case of, and

formally equivalent to, the general process of updating of reward predictions.

Although the Rescorla-Wagner rule models the acquisition of predictions (V in *Equation 2*), it does not conceptualize predictions as conditioned, higher order reinforcers. However, higher order reward properties are responsible for most reward functions in learning, approach behavior, and emotional reactions, as outlined above (640). The temporal difference (TD) reinforcement model in machine learning captures the learning functions of higher order rewards (574). Its prediction error includes both unconditioned and higher order reinforcers, without distinguishing between them, as

$$\mathrm{TDPE}(t) = [\lambda(t) + \gamma\sum \mathrm{V}(t)] - V(t-1) \quad (4)$$

The t stands now for time step within a given trial, γ is a temporal decay (discounting) factor. A temporal, rather than trial by trial, prediction error is adequate when including higher order reinforcers that derive from reward predictors and necessarily occur at earlier times than unconditioned reinforcers. The term $[\lambda(t) + \gamma\sum \mathrm{V}(t)]$ replaces the $\lambda(t)$ term in *Equation 1* and incorporates at every time step t the unconditioned reward $\lambda(t)$ and the discounted (γ) sum ($\sum$) of future rewards predicted by $\mathrm{V}(t)$ serving as higher order reward. The TDPE includes a higher order prediction error that indicates how much the reward predicted by a conditioned stimulus varies relative to an earlier reward prediction. Thus TDPEs are generated by successive conditioned stimuli to the extent that these stimuli carry different reward predictions than the preceding stimulus.

Substituting PE of *Equation 2* by TDPE of *Equation 4* leads to the TD learning model

$$\mathrm{V}(t+1) = \mathrm{V}(t) + \alpha * \mathrm{TDPE}(t) \quad (5)$$

Thus TD learning advances backwards from an unconditioned reward to the earliest reward predictor. Updating of the earliest reward prediction employs the prediction value of the subsequent stimulus and does not need to wait for the final, unconditioned reward. Thus each of the conditioned, reward-predicting stimuli serves as a higher order reward, which is biologically plausible by reflecting the frequent occurrence of conditioned rewards and addressing the often difficult distinction between the primary or conditioned nature of natural rewards (640). The use of truly unconditioned rewards in TD learning is straightforward (573). TD reinforcement models are efficient and learn complex tasks involving sequential states, like balancing a pole on a moving platform (32) or playing backgammon (586).

4. Dopamine reward prediction error signal

Most midbrain dopamine neurons show rather stereotyped, phasic activations with latencies of <100 ms and durations of <200 ms following unpredicted food or liquid rewards **(FIGURE 7, *A* AND *B*)**. The response codes the prediction error, namely, the quantitative difference between received and predicted reward value in each trial t, which can be generically be expressed as

$$\mathrm{DaResp}(t) \sim \lambda(t) - \mathrm{V}(t) \quad (6)$$

The neuronal response is bidirectional, as a reward that is better than predicted elicits an activation (positive prediction error response) and a reward that is worse than predicted induces a depression (negative error response) in monkeys, rats, and mice **(FIGURE 7*C*)**. A fully predicted reward draws no response. These responses occur with all-or-none reward prediction errors (321, 365, 410, 503, 517, 521, 524), and with graded, quantitative prediction errors (more or less reward than predicted) (33, 102, 144, 161, 376, 598). Thus the dopamine response codes a reward prediction error (*Equation 1*) that may constitute a biological instantiation of the reinforcement term in Rescorla-Wagner learning (365), TD learning (374), and spectral timing (71).

The negative dopamine reward prediction error response consists of a depression of activity against low background activity. Adequate assessment requires measuring impulse rate over the maximal length of the depression (34), thus avoiding an almost ungraded negative response (33). Even with a graded negative response (161), the negative error response has less dynamic range than the positive error response. However, the complete cessation of dopamine activity for varying durations may have stronger impact on postsynaptic neurons than graded increases and thus may compensate for the limited dynamic range. Even before it comes to synaptic transmission, voltammetrically measured dopamine concentration changes resulting from negative reward prediction errors are symmetric to the changes resulting from positive errors (204). Thus the dopamine reward prediction error signal seems to be bidirectional.

Dopamine responses show features beyond the Rescorla-Wagner learning rule. About one-third of dopamine neurons show also slower activations preceding reward that vary with the standard deviation (risk) of reward probability distributions (161). The risk response reflects the unsigned (absolute) prediction error and, in keeping with the attentional learning rules (425), may affect learning rate α (*Equation 3*) and thus serve to adjust learning speed. Furthermore, the prediction error response itself scales with the standard deviation of reward probability distributions (598) according to *Equation 3B*, which may be driven by the slower activation coding standard deviation and serve to achieve comparable learning with different standard deviations. Third, the prediction error response is sensitive to predictions in model-based learning (see below).

The dopamine response at the time of reward fulfils stringent tests for prediction errors conceptualized by animal

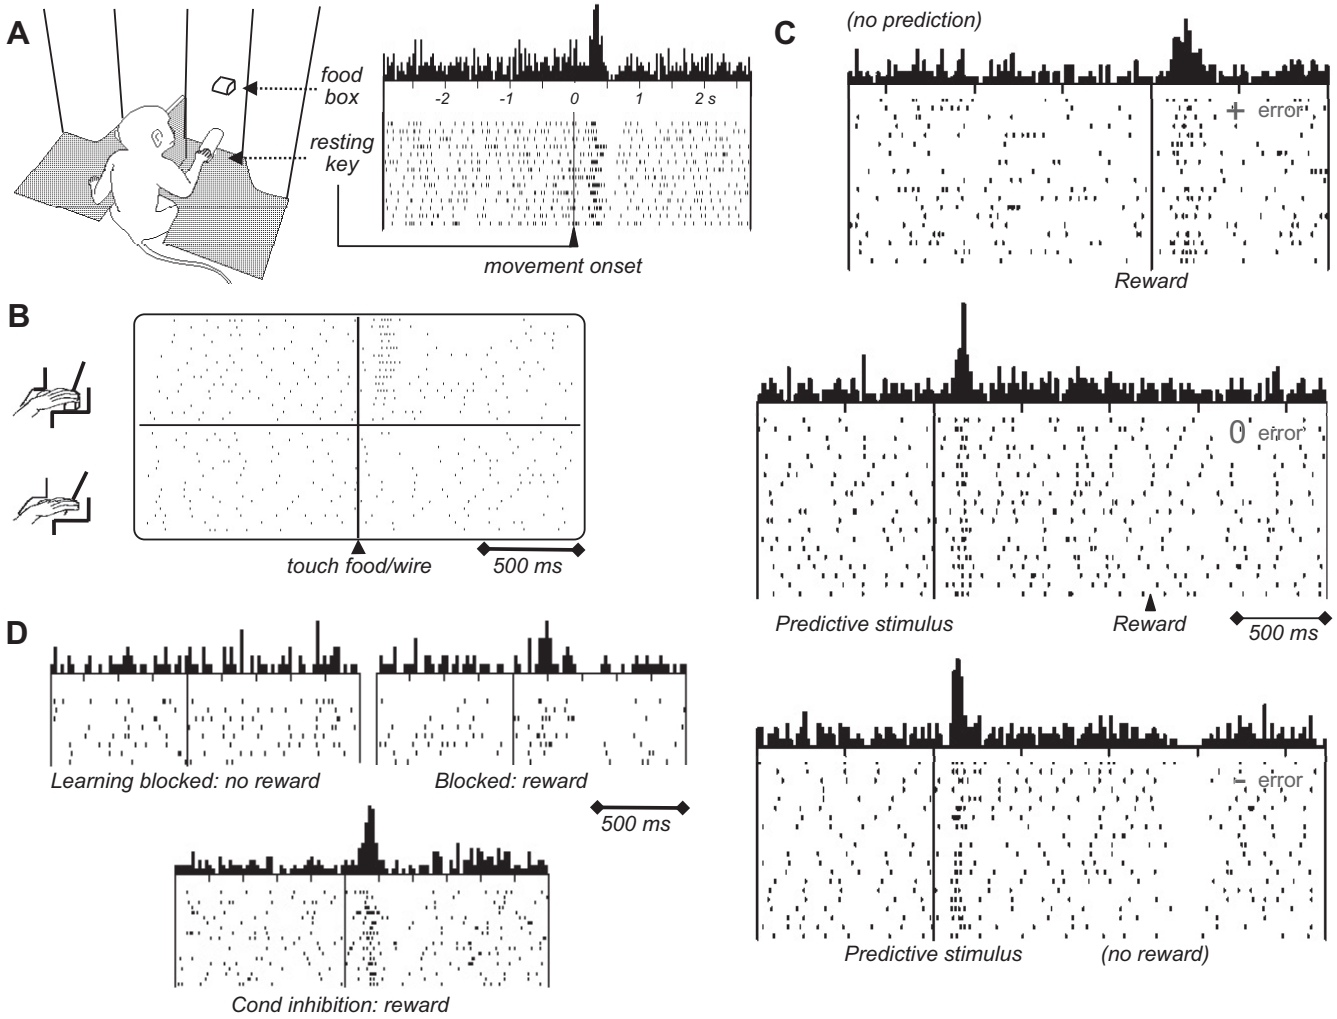

FIGURE 7. Dopamine prediction error responses at the time of reward in monkeys. *A:* dopamine responses to touch of food without any phasic stimuli predicting the reward. The food inside the box is invisible but is touched by the hand underneath the cover. Movement onset is defined as release of resting key. *B:* differential response to touch of a piece of apple (*top*) but not to touch of a bare wire (*bottom*) or known inedible objects. Left graphs show the animal's hand entering the covered food box. Inside the box, touch of a bare wire or a wire holding the food elicits an electric signal for temporal reference (vertical line at right). [*A* and *B* from Romo and Schultz (491), with kind permission from Springer Science and Business Media.] *C:* reward prediction error responses at time of reward (*right*) and reward-predicting visual stimuli (left in 2 bottom graphs). The dopamine neuron is activated by the unpredicted reward eliciting a positive reward prediction error (blue + error, *top*), shows no response to the fully predicted reward eliciting no prediction error (0 error, *middle*), and is depressed by the omission of predicted reward eliciting a negative prediction error (- errror, *bottom*). [From Schultz et al. (524).] *D:* reward prediction error responses at time of reward satisfy stringent prediction error tests. *Top*: blocking test: lack of response to reward absence following the stimulus that was blocked from learning (*left*), but activation by surprising reward after blocked stimulus (*right*). [From Waelti et al. (618).] *Bottom*: conditioned inhibition test. Supranormal activation to reward following an inhibitory stimulus explicitly predicting no reward. [From Tobler et al. (597).]

learning theory **(FIGURE 7*D*)**. In the blocking test, a test stimulus is blocked from acquiring reward prediction when the reward is fully predicted by another stimulus (zero contingency). If reward does occur after the nonpredictive test stimulus, it will produce a positive prediction error, and dopamine neurons are activated by that reward (618). In the conditioned inhibition test, a reward occurring after a stimulus explicitly predicting reward absence elicits a super strong positive reward prediction error (because of a negative prediction being subtracted from the reward, *Equation 1*), and dopamine neurons accordingly show supranormal activation by the surprising reward (*Equation 6*) (598). Thus the phasic dopamine responses follow the formal theoretical requirements for prediction error coding.

Reward-predicting stimuli induce phasic activations in most dopamine neurons (60-75%) **(FIGURE 7*C*)** (322, 503) and increase correlations between dopamine impulses (256). These responses are gradually acquired through

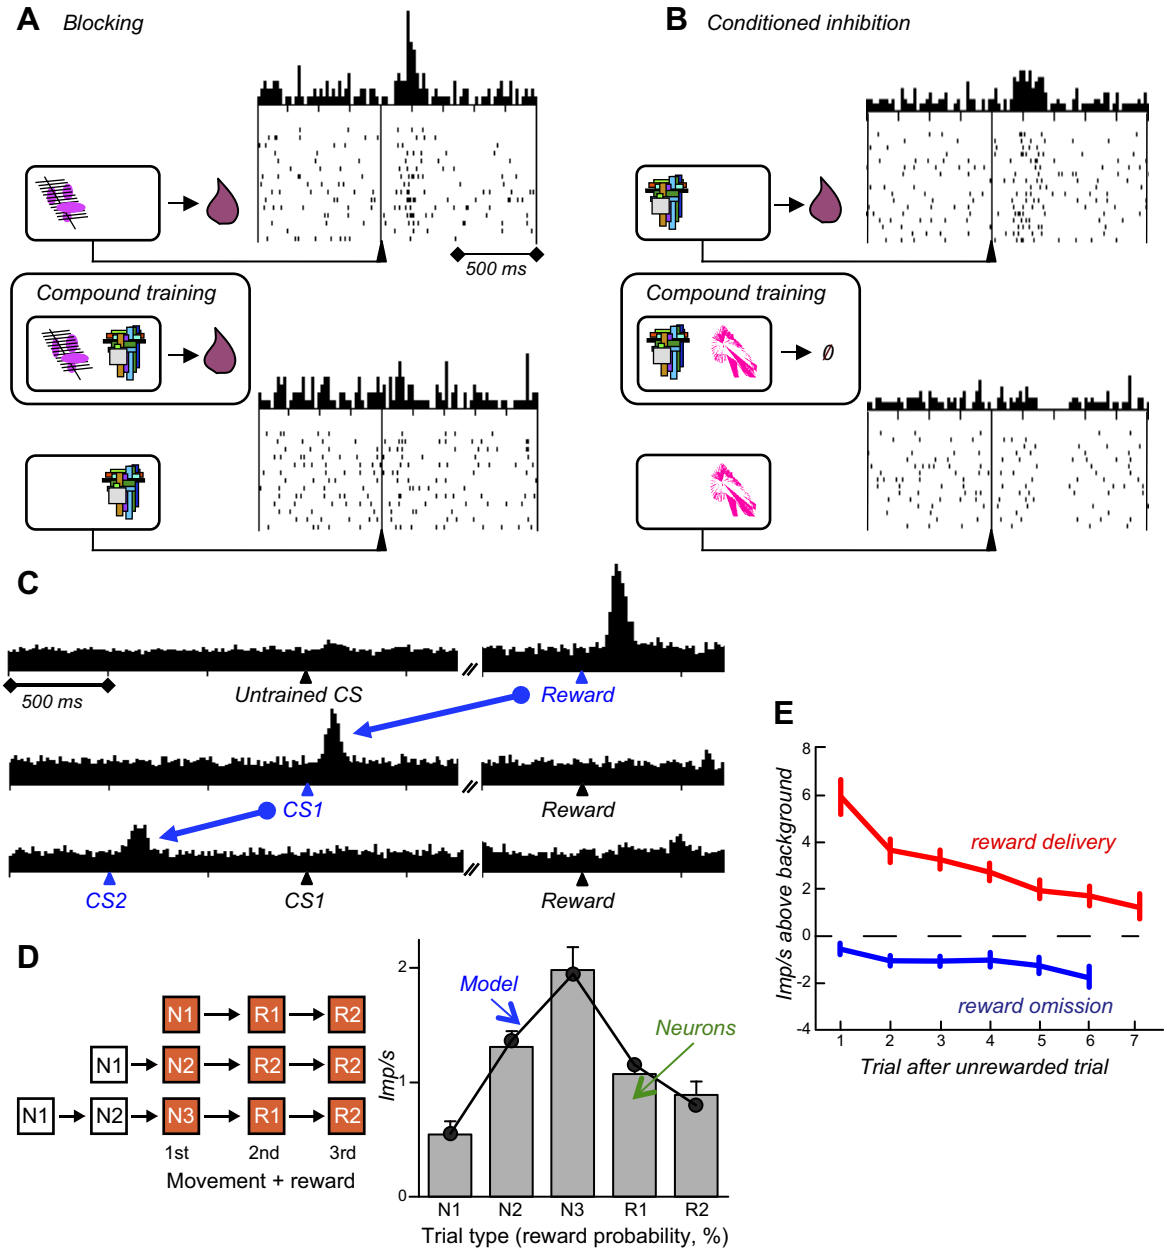
learning and thus code the prediction V of Rescorla-Wagner and TD models. Correspondingly, voltammetrically measured striatal dopamine release shifts from reward to reward-predicting stimuli during conditioning (117). Acquisition of dopamine responses to conditioned stimuli requires prediction errors, as the blocking test shows. Compounding a novel stimulus with an established reward predictor without changing the reward fails to elicit a prediction error and prevents the stimulus from being learned **(FIGURE 8*A*)**. A conditioned inhibitor elicits a depressant instead of an activating response **(FIGURE 8*B*)**.

Results from tests with sequential reward-predicting stimuli suggest that dopamine responses signal higher order reward prediction errors compatible with TD learning (374). Thus the dopamine responses are well described by extending *Equation 6* and using *t* as time steps, which can be generically be expressed as

$$\mathrm{DaResp}(t) \sim [\lambda(t) + \gamma\sum \mathrm{V}(t)] - \mathrm{V}(t-1) \quad (7)$$

The dopamine response jumps sequentially backwards from the "unconditioned" liquid reward via stimuli predicting this reward to the earliest reward-predicting stimulus, while losing the response to the predicted intermediate stimuli and the predicted reward **(FIGURE 8*C*)** (453, 521). Similar to TD learning, the dopamine responses do not distinguish between primary and higher order reward prediction errors. Only their magnitudes, and fractions of responding neurons, decrease due to temporal discounting, which in TD learning is incorporated as γ. With several consecutive conditioned stimuli, dopamine neurons code the TD prediction error exactly as the predicted value changes between the stimuli (398). In such tasks, dopamine responses match closely the temporal profiles of TD errors that increase and decline with sequential variations in the discounted sum of future rewards **(FIGURE 8*D*)** (144). Thus dopamine neurons code reward value at the time of conditioned and unconditioned stimuli relative to the reward prediction at that moment.

The reward-predicting instruction stimuli in delay tasks have little incentive properties and thus provide a distinction between predictive and incentive stimulus properties (see above). These instructions contain information and elicit saccadic eye movements for acquiring the information contained in the stimulus, but the animal is not allowed to react immediately with a movement towards a rewarded target; it must wait for a later, incentive, movement-triggering stimulus. The consistent dopamine responses to these predictive instructions **(FIGURE 8*C*)** (301, 349, 453, 521, 527, 579), and their lack of ocular relationships (527), suggest predominant coding of predictive stimulus properties, without requiring incentive properties. In contrast, in specific sign- and goal-tracking rat strains, striatal voltammetric dopamine responses are stronger to stimuli with incentive compared with reward-predictive properties (163). These differences may be due to different methods (electrophysiological impulses vs. voltammetric dopamine concentrations) and genetic differences in the specifically bred sign versus goal trackers differentially affecting the dopamine response transfer from reward to predictive stimulus.



Hundreds of human neuroimaging studies demonstrate activations induced by reward related stimuli and reward-related actions in the main reward structures (280, 590). A BOLD neuromagnetic (fMRI) signal reflecting reward prediction error is found in the ventral striatum (351, 390) and constitutes probably the most solid reward response in the brain. It likely reflects the dopamine prediction error signal, as it increases with dopamine agonists and decreases with dopamine antagonists (431). It is detected more easily in striatal and frontal dopamine terminal areas than in midbrain cell body regions (111, 431, 615), because it presumably reflects summed synaptic potentials (328), which may be stronger after the massive axon collaterilization in the striatum. The human reward signal allows also to assess neuronal correlates of positive emotional reward functions, which is intrinsically difficult in animals despite recent efforts (44). With the use of raclopride binding with positron emission tomography (PET), amphetamine-induced dopamine concentrations correlate highly with subjective euphoria ratings in ventral (but not dorsal) striatum (140). BOLD responses in ventral striatum correlate with pleasantness ratings for thermal stimuli (along with orbitofrontal and anterior cingulate activations) (486) and with momentary happiness ratings derived from a combination of certain rewards, gambles, and reward prediction errors (along with anterior cingulate and anterior insula activations) (498). These responses in the dopamine receiving striatum suggest a role of dopamine in signaling pleasure and happiness.

5. Dopamine error signal incorporates model-based predictions

Standard conditioning occurs through prediction errors derived from actually experienced outcomes. However, individuals also learn about contexts, situations, rules, sequences, and conditional probabilities, which may be summarily called models of the world. Knowledge derived from such models can affect the prediction in the neuronal prediction error computation, result in a more appropriate teaching signal, and thus tremendously improve learning.

Model-based learning involves two separate processes, the acquisition and updating of the model, and the influence of the model on reinforcement learning, which likely occurs by influencing predictions of the outcome (139, 575). The acquisition and updating of some of the models likely involves cortical rather than dopamine signals. In contrast, dopamine responses seem to incorporate the predictive information from models once they are established.

In one such experiment, sequences of unrewarded trials lead to higher conditional reward probability with increasing trials (increasing hazard function). The underlying temporal structure constitutes a model in which reward prediction increases progressively. Due to increasing reward prediction, later reward delivery induces increasingly weaker positive prediction errors, and reward omission elicits stronger negative prediction errors. In contrast, model-free reinforcement learning would only consider the past unrewarded trials and hence generate progressively decreasing reward prediction and an opposite pattern of errors. In this experiment, dopamine prediction error responses decrease with increasing numbers of trials since the last reward and thus reflect the increasing reward prediction **(FIGURE 8*E*)** (382). In another experiment, dopamine reward prediction error responses adapt to previously learned reward probability distributions (598). The responses scale to expected value and standard deviation and show similar magnitudes with 10-fold differences in reward magnitude. In another example of model-based learning, acquisition of a reversal set allows animals to infer reward value of one stimulus after a single reversed trial with the other stimulus. Accordingly, dopamine prediction error responses reflect the inferred reversed reward prediction (68). In each of these examples, the observed dopamine prediction error responses are not fully explained by the immediate experience with reward but incorporate predictions from the task structure (model of the world). Thus dopamine neurons process prediction errors with both model free and model-based reinforcement learning.

6. Dopamine response in cognitive tasks

Bidirectional dopamine prediction error responses occur also in tasks with elaborate cognitive components. Dopamine neurons, and their potential input neurons in lateral habenula, show bidirectional prediction error responses that signal values derived from differential discounting with conditioned reinforcers (66, 67), although concurrent risk influences on subjective value need to be ruled out. More complex tasks require distinction of many more possible confounds. Early studies used spatial delayed, spatial alternation, and delayed matching-to-sample tasks typical for investigating neurons in prefrontal cortex and striatum and report positive and negative prediction error responses to rewards and reward-predicting stimuli compatible with TD learning models (321, 521, 579). Similar dopamine error responses occur in tasks employing sequential movements (503), random dot motion (389), and somatosensory detection (122). Advanced data analyses from these complex tasks reveal inclusion of model-based temporal predictions into the dopamine error response (382) and compatibility with TD models (144). Variations in stimulus coherence (389) and visual search performance (349) result in graded reward probabilities that induce reward prediction errors that are coded by dopamine neurons, although the error coding may not be easily apparent (426). Thus, in all these high-order cognitive tasks, the phasic dopamine response tracks only, and reliably, the reward prediction error.

7. Dopamine event detection response

The dopamine reward prediction error response is preceded by a brief activation that detects any sufficiently strong event before having identified its reward value (**FIGURE 9, *A–C***, blue areas). The early response component occurs with latencies of <100 ms with all sensory modalities, including loud noises, light flashes, and rapidly moving visual stimuli (229, 322, 527, 563) and evokes dopamine release (117). The activation reflects the sensory impact and physical salience of rewards, punishers, and their predictive stimuli (157, 159, 160). It does not fully reflect motivational salience, as it is absent with negative motivating events of low sensory impact (160, 366), negative reward prediction errors (321, 517, 521, 524, 597, 618), and conditioned inhibitors (597). The detection response covaries inversely with the hazard rate (of temporal event occurrence) and thus codes surprise salience (286) or a temporal prediction error (389) as conceptualized in TD models (574). Thus the early dopamine response component reflects the detection of an event before having identified its value.

This initial response component develops into the graded reward prediction error response, which ranges from depression with strong negative prediction errors to strong activation with positive prediction errors (158, 285, 301, 376, 597). The transition from the first to the second response component depends on the time necessary for assessing the value of the stimulus and thus may vary considerably between behavioral tasks. With easy identification, the transfer takes ~50 ms and fuses the two components, for example, when fixed stimulus positions allow rapid stimulus identification without eye saccades (**FIGURE 9, *A* AND *B***). Then the two components are fused and may appear as a single response whose identity has long been unclear and may occasionally be labeled as attentional (355, 356). A possible intermediate sensory identification step is either not discernible or is not engaging dopamine neurons. In contrast, the components separate into two separate responses with slower stimulus identification, as seen with random dot motion stimuli requiring >200 ms behavioral discrimination time (**FIGURE 9*C***) (389). Thus the early dopamine activation detects events rapidly before identifying them properly, whereas the subsequent bidirectional response component values the event and codes a proper reward prediction error.

The accurate value coding by the second response component is reflected in the error response at the time of the reward (398, 618). Despite the initial dopamine activation by an unrewarded stimulus, a subsequent reward is registered as a surprise eliciting a positive prediction error re-

FIGURE 8. Dopamine responses to conditioned stimuli in monkeys. *A*: stimulus responses of a single dopamine neuron during a blocking test. A pretrained stimulus predicts liquid reward and induces a standard dopamine response (*top*). During compound training, a test stimulus is shown together with the pretrained stimulus while keeping the reward unchanged (*middle left*). Thus the reward is fully predicted by the pretrained stimulus, no prediction error occurs, and the test stimulus is blocked from learning a reward prediction. Correspondingly, the test stimulus alone fails to induce a dopamine response (*bottom*). [From Waelti et al. (618).] *B:* stimulus responses of a single dopamine neuron during a conditioned inhibition test. The reward normally occurring with the pretrained stimulus (*top*) fails to occur during compound training with a test stimulus (*middle left*). This procedure makes the test stimulus a predictor of no reward which correspondingly induces a dopamine depression (*bottom*). [From Tobler et al. (597).] *C:* stepwise transfer of dopamine response from reward to first reward-predicting stimulus, corresponding to higher order conditioning conceptualized by temporal difference (TD) model. CS2: instruction, CS1: movement releasing (trigger) stimulus in delayed response task. [From Schultz et al. (521).] *D:* reward prediction error responses closely parallel prediction errors of formal TD model. *Left*: sequential movement-reward task. One or two stimuli (white N1, N2) precede the movements leading to reward (orange, 1st, 2nd, 3rd). *Right*: averaged population responses of 26 dopamine neurons at each sequence step (gray bars, numbers indicate reward probabilities in %) and time course of modeled prediction errors $\{[\lambda(t) + \gamma\sum V(t)] - V(t-1)\}$ (black line). [From Enomoto et al. (144).] *E:* dopamine prediction error responses reflect model-based reward prediction derived from temporal task structure. The model specifies an increase in conditional reward probability P(reward | no reward yet) from initial $P = 0.0625$ to $P = 1.0$ after six unrewarded trials. Correspondingly, positive prediction errors with reward occurrence decrease across successive trials, and negative errors with reward omission increase. Averaged population responses of 32 dopamine neurons show similar temporal profiles (blue and red, as impulses/s above neuronal background activity). [From Nakahara et al. (382), with permission from Elsevier.]

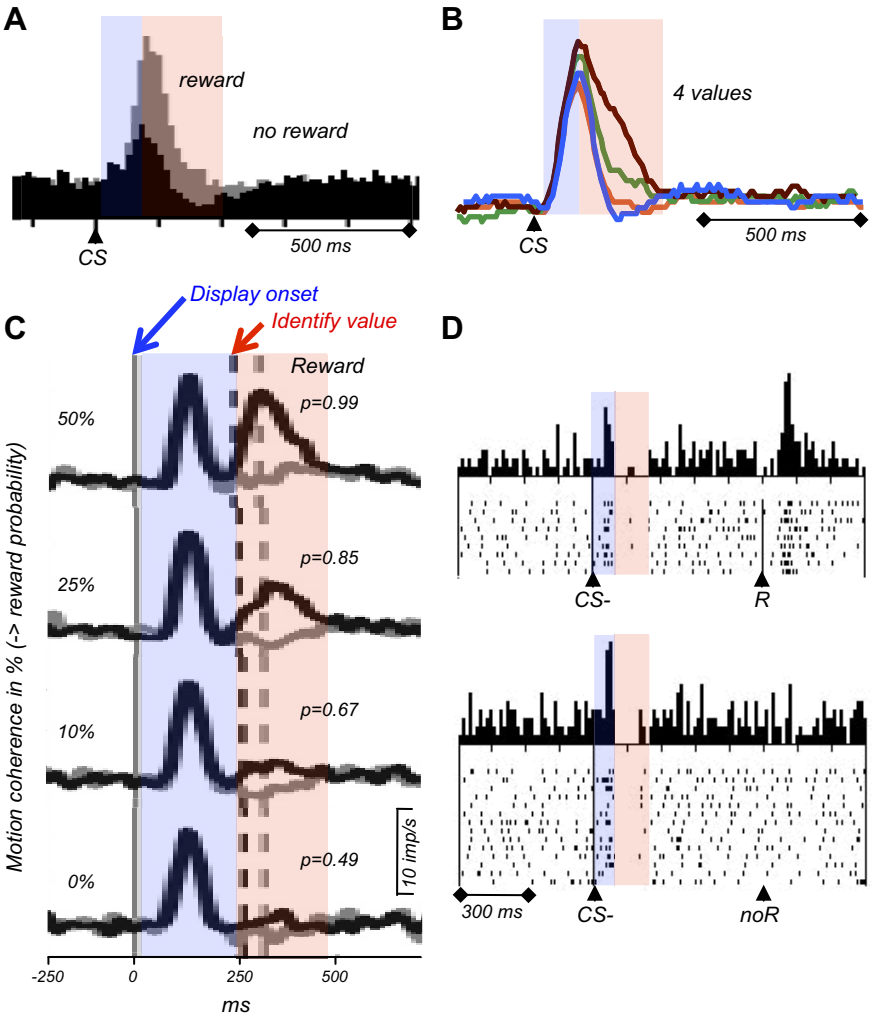


FIGURE 9. Two components of phasic dopamine responses. *A:* averaged population responses of 69 monkey dopamine neurons to conditioned stimuli (CS) predicting reward (gray) and no reward (black). Note the initial indiscriminate detection response component (blue) and the subsequent reward response component distinguishing between reward and no reward prediction (red). [From Tobler et al. (597).] *B:* averaged population responses of 54 monkey dopamine neurons to conditioned stimuli (CS) predicting rewards at different delays (2, 4, 8, and 16 s; brown, green, orange, and blue, respectively). The value reduction due to temporal discounting affects only the second, reward prediction error component (red). [From Kobayashi and Schultz (285).] *C:* differentiation of dopamine response into initial detection response and subsequent prediction error response. Increasing motion coherence (from 0 to 50%) improves binary dot motion discrimination and translates into increasing reward probability (from $P = 0.49$ to $P = 0.99$). The first response component is nondifferentially constant (blue), whereas the second component grows with increasing reward value (derived from probability, *bottom* to *top*, red). [From Nomoto et al. (389).] *D:* accurate value coding at time of reward despite initial indiscriminate stimulus detection response. After the unrewarded conditioned stimulus (CS-), surprising reward (R) elicits a positive prediction error response (*top*), whereas predicted reward absence (noR) fails to elicit a negative error response (*bottom*). [From Waelti et al. (618).]

sponse (**FIGURE 9*D***, *top*); accordingly, reward absence fails to induce a negative prediction error response (**FIGURE 9*D***, *bottom*). Thus, from the second response component on, and before a behavioral reaction can occur, dopamine responses accurately reflect the unrewarded stimulus nature. This constitutes the information postsynaptic neurons are likely to receive, which may explain why animals do not show generalized behavioral responses despite initial neuronal response generalization.

The initial dopamine detection response component varies with four factors. First, it increases with the sensory impact of any physical event, which confers physical salience (**FIGURE 10*A***) (160). This is most likely what the early studies on dopamine salience responses observed (229, 322, 563). Second, also involving memory processing stages, the dopamine detection component is enhanced by stimulus novelty (conferring novelty salience) (322) or surprise (conferring surprise salience) (255, 286, 345). Although novelty may constitute outright reward (458), dopamine neurons are not activated by novelty per se but require stimuli with sufficient sensory impact. The neurons do not respond to small novel stimuli, even though they show prediction error responses to the same small stimuli after learning (597, 618). The total dopamine response decreases with stimulus repetition, together with the animal's ocular orienting responses, and increases again with reward prediction learning (**FIGURE 10*B***) (517). Third, the dopamine detection component increases with generalization to rewarded stimuli, even when animals discriminate behaviorally well between them. The neuronal generalization is analogous to generalization in behavioral conditioning when an unconditioned stimulus resembles closely a conditioned stimulus and the "associative strength" spills over (335). The incidence of activations to unrewarded, including aversive, stimuli increases with closer similarity and same sensory modality as rewarded stimuli (527, 597, 618). A change from auditory to visual modality of the rewarded stimulus, while leaving the visual aversive stimulus unchanged, increases the initial activations from <15 to 65% of dopamine neurons (**FIGURE 10*C***) (366). Generalization likely also induces motivational salience via similar positively valued stimuli. Generalization may explain the more frequent dopamine activations to conditioned compared with primary aversive stimuli (345), which defies basic learning concepts. The initial response component evoked by reward

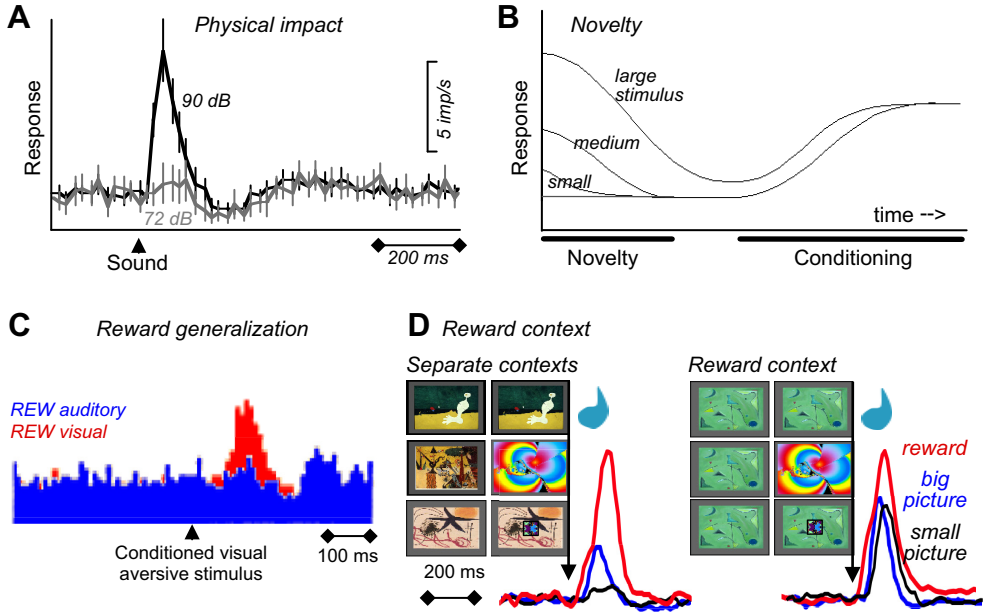

FIGURE 10. Four factors influencing the detection component of phasic dopamine responses. *A:* detection response generated by sensory impact, conferring physical salience. Louder, nonaversive sounds with higher physical salience generate stronger activations (72 and 90 dB, respectively; behavioral choice preferences demonstrated their nonaversive nature). Averaged population responses measured as impulses/s (imp/s) of 14 and 31 monkey dopamine neurons, respectively. [From Fiorillo et al. (160).] *B:* detection response, and possibly also second response component, enhanced by stimulus novelty, conferring novelty or surprise salience. Stimulus novelty itself is not sufficient to induce dopamine activations, as shown by response absence with small stimuli (horizontal line), but enhances detection response when stimuli are physically larger and more salient (vertical axis). Neuronal responses wane with stimulus repetition due to loss of novelty and increase again with conditioning to reward (from *left* to *right*). [Composite scheme from Schultz (517), derived from original data (221, 597, 618).] *C:* detection response enhanced by generalization to rewarded stimuli. Blue: minor population response to conditioned visual aversive stimulus alternating with auditory reward-predicting stimulus (REW auditory) (active avoidance task). Red: substantial activation to identical visual aversive stimulus when the alternate reward-predicting stimulus is also visual (REW visual), a situation more prone to stimulus generalization. As control, both auditory and visual reward-predicting stimuli induce typical dopamine activations (not shown). [From Mirenowicz and Schultz (366).] *D:* detection response enhanced by reward context. *Left* (separate contexts): minor dopamine population activations induced by unrewarded big and small pictures when non-reward context is well separated from reward context by testing in separate trial blocks, using distinct background pictures and removing liquid spout in picture trials. *Right* (common reward context): major activations by same unrewarded pictures without separation between non-reward and reward context. [From Kobayashi and Schultz (286).]

generalization induces dopamine release in nucleus accumbens (117). Fourth, the dopamine detection component increases in rewarding contexts (286), via pseudoconditioning or higher order context conditioning (367, 536, 537), without explicit reward pairing. Accordingly, reducing the separation between unrewarded and rewarded trials, and thus infecting unrewarded trials with reward context, boosts the incidence of dopamine activations to unrewarded stimuli (from 3 to 55% of neurons) **(FIGURE 10*D*)** (286), as does an increase of reward from 25 to 75% of trials (from 1 to 44% of neurons) (597, 618). Thus the initial response component reflects the detection of environmental events related to reward in the widest possible way, which conforms well with the reward function of the phasic dopamine signal.

Other neuronal systems show similar temporal evolution of stimulus responses. During visual search, frontal eye field neurons respond initially indiscriminately to target and distractor and distinguish between them only after 50–80 ms (see below, **FIGURE 38*B***) (588). Neurons in primary visual cortex V1 take 100 ms after the initial visual response to show selective orientation tuning (468) and spatial frequency selectivity (61). Over a time course of 140 ms, V1 neurons initially detect visual motion, then segregate the figure created by dot motion from background motion, and finally distinguish the relevant figure from a distractor (474). V1 and frontal eye field neurons respond initially indiscriminately to targets and distractors and distinguish between them only after 40–130 ms (434). During perceptual decision making, LIP and prefrontal neurons respond initially indiscriminately to stimulus motion and distinguish between motion strength only at 120–200 ms after stimulus onset (see below, **FIGURE 38*A***) (274, 483, 535). Pulvinar neurons show initial, nondifferential detection responses and subsequent differential stimulus ambiguity responses

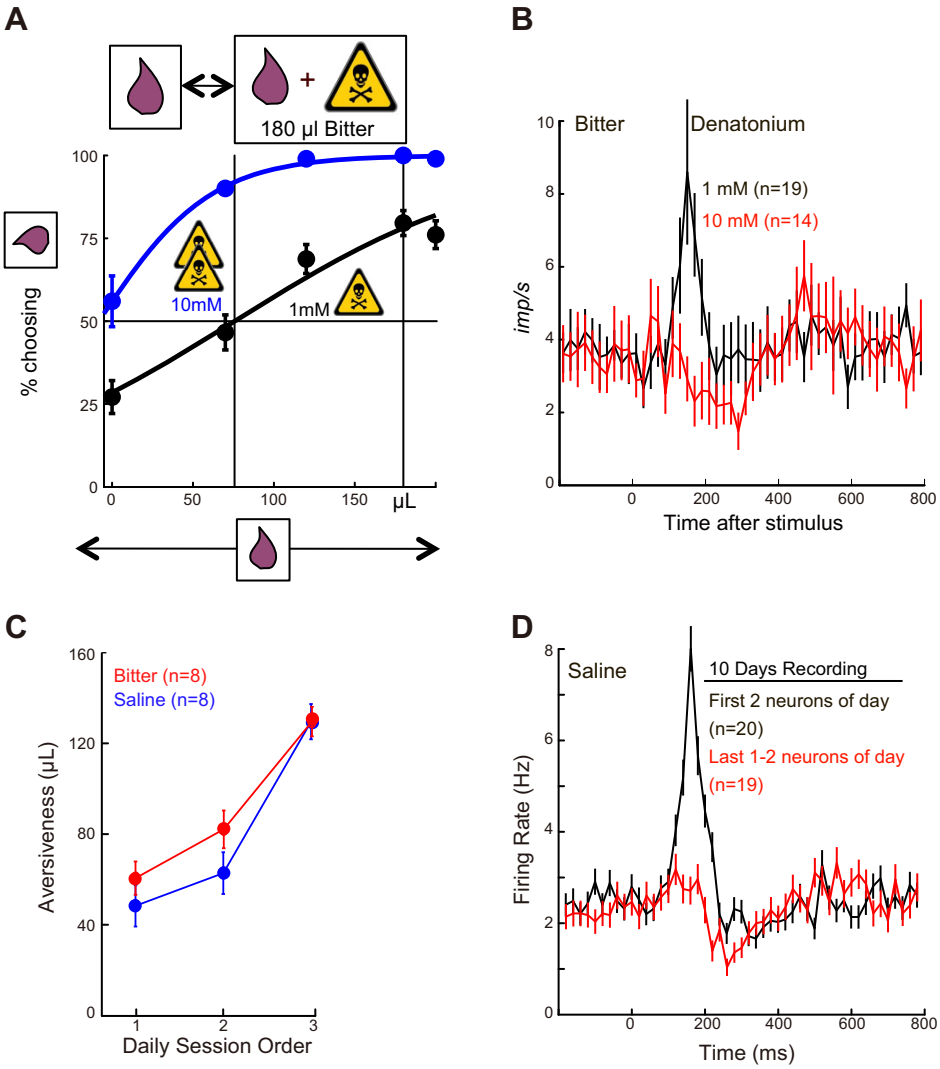

FIGURE 11. No aversive coding in monkey dopamine activations. *A:* psychophysical assessment of aversiveness of bitter solution (denatonium) as prerequisite for investigating quantitative neuronal processing of aversiveness. Monkey chose between single juice reward and juice reward + denatonium (*top*). The blue and black psychophysics curves show that increasing the volume of single juice reward induces more frequent choices of this reward against constant alternative juice + denatonium. Aversiveness of denatonium is expressed as difference between volume of single juice and juice together with denatonium at choice indifference (50% choice). Thus 1 mM denatonium is worth −100 µl of juice (black), and 10 mM denatonium is worth −180 µl (blue). The *x*-axis shows volume of single juice, and *y*-axis shows percent of choices of single juice. *B:* inverse relationship of neuronal activations to psychophysically quantified aversiveness of bitter solutions (behavioral method shown in *A*). *N* = number of neurons. Imp/s indicate firing rate. *C:* development of behavioral aversiveness of solutions within individual test days, as assessed with method shown in *A*. Liquid solutions of salt or bitter molecules lose reward value through gradual satiation and thus become increasingly aversive (thirsty monkeys work for mildly "aversive" saline solutions, and thus find them rewarding, as outcome value is dominated by liquid over salt). *D:* decreasing dopamine activations with increasing aversiveness of saline solution within individual test days (behavioral aversiveness assessment shown in *C*), suggesting subtraction of negative aversive value from gradually declining juice value due to satiation. [*A–D* are from Fiorillo et al. (160).]

during visual categorization (288). Tactile responses in mouse barrel cortex require 200 ms to become differential (300). Similar multicomponent responses are seen with reward coding. Amygdala neurons initially detect a visual stimulus and may code its identity and then transition within 60–300 ms to differential reward value coding (9, 422, 428). V1 and inferotemporal cortex responses show initial visual stimulus selectivity and only 50–90 ms later distinguish reward values (371, 557). Thus there is a sequence in the processing of external events that advances from initial detection via identification to valuation. Whereas sensory processing involves only the first two steps, reward processing requires in addition the third step.

8. No aversive dopamine activation

Aversive stimuli are well known for >30 years to activate 10–50% of dopamine neurons in awake and anesthetized monkeys, rats, and mice (102, 193, 255, 345, 362, 366, 525, 604) and to enhance dopamine concentration in nucleus accumbens (75). Five neurons close to juxtacellularly labeled ventral tegmental area (VTA) dopamine neurons were activated by footshocks (64), similar to the effects of airpuffs and footshocks on non-dopamine neurons in the area (102, 582). The activations may have derived from dopamine neurons or not; the 30–45% of dopamine neurons lacking spontaneous activity (76, 166, 176, 211) may include nonactivated neurons and thus go undetected while taking up the label. In monkeys, some putative dopamine neurons, often located above substantia nigra, are activated by air puffs (345), although they respond more frequently to conditioned stimuli than primary rewards and thus defy the higher aversiveness of primary than conditioned punishers. However, just as rewards, punishers have distinct sensory, attentional, and motivating components, and none of these studies has distinguished between them. A recent psychophysical study that made this distinction by varying these components independently reports that dopamine activations by aversive stimuli reflect the physical, sensory stimulus impact rather than their aversiveness **(FIGURE 11)** (160). Once the sensory impact is controlled for, the aversive nature of stimuli either fails entirely to affect dopamine

neurons (157), reduces the total reward value of liquid solutions and their evoked dopamine activations (157, 160), and induces outright depressant dopamine responses (73, 102, 345, 362, 366, 608). In awake animals, the aversive nature of stimuli does not generate dopamine activations, but induces negative reward prediction errors either because of the negative value or by not being rewarding, and correspondingly induces depressant dopamine responses (157). Thus the different fractions of "aversively" activated dopamine neurons seen in earlier studies likely reflect the different intensities of physical stimuli employed (159). The graded activations with punisher probability (345) might reflect salience differences of conditioned stimuli (286), or graded anticipatory relief to punisher termination (75) that is considered as rewarding (552). Salience, rather than negative reinforcer value, might also explain the surprising higher incidence of activations to conditioned stimuli compared with primary punishment (345). The sensory rather than negative value nature of dopamine responses to aversive stimuli would also explain the dopamine activations by aversive stimuli under anesthesia (64, 525, 604) where motivational impact is ruled out.

The "aversive" dopamine activation constitutes a short latency response that is shorter than the reward response, is substantially boosted by generalization from rewarded stimuli, and is often curtailed by a subsequent depression (366). With these characteristics, the aversive dopamine activations seem to constitute the initial dopamine detection response that reflects mostly physical salience. In agreement with this interpretation, the aversive dopamine neurons are also driven by rewards and unrewarded stimuli and thus are highly sensitive to a large range of stimuli (366) compatible with coding physical impact rather than motivational value. Furthermore, dopamine neurons are neither depressed nor activated by negative aversive prediction errors (157, 255, 345), and show only enhanced activations with positive aversive prediction errors possibly reflecting surprise salience. Thus the current evidence suggests that aversive stimuli activate some dopamine neurons through physical impact rather than through their negative, aversive motivational value, although some dopamine neurons with truly aversive activations can never be completely ruled out.

9. Comprehensive account of phasic dopamine response

Of the two phasic dopamine response components **(FIGURE 12)**, the initial detection activation occurs before the neurons have identified the current reward value of the stimulus and arises even with motivationally neutral events and punishers. It increases with sensory impact, novelty, reward generalization, and rewarded contexts. Thus the initial component detects potential rewards and provides an early report before having identified the value of the event properly, which relates closely to the reward coding of dopamine neurons. The second response component arises once the

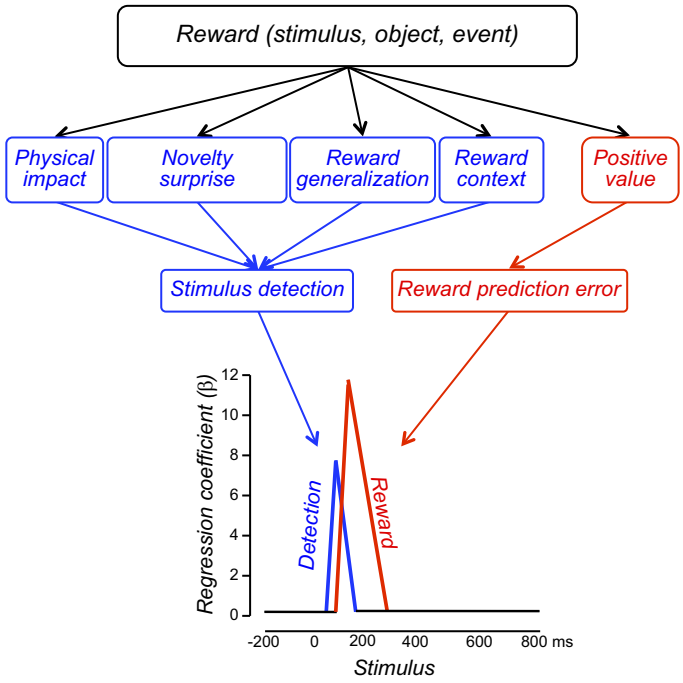

FIGURE 12. Reward components inducing the two phasic dopamine response components. The initial component (blue) detects the event before having identified its value. It increases with sensory impact (physical salience), novelty (novelty/surprise salience), generalization to rewarded stimuli, and reward context. This component is coded as temporal event prediction error (389). The second component (red) codes reward value (as reward prediction error).

neurons have well identified the reward value of the stimulus and codes only reward. As longest and strongest component it constitutes the major phasic dopamine influence on postsynaptic processing. The two components are integral parts of the dopamine reward prediction error response, which seems to be split into an early temporal error component and a subsequent value error component (also time sensitive), thus providing an interesting biological instantiation of a TD reinforcement teaching signal (574).

The phasic dopamine reward signal is homogeneous in latency, duration, and sensitivity across different dopamine neurons and very similar between different rewards, thus contrasting sharply with the widely varying reward processing in other brain structures. Graded variations in dopamine responses derive from the initial detection response component that varies in a continuous manner across the mediolateral or dorsoventral extent of the ventral midbrain. If this graded initial component occurs with aversive stimuli and is interpreted as aversive rather than detection response, some dopamine neurons may seem categorically different from those showing a smaller or no detection component (64, 255), suggesting neuronal response heterogeneity (345). However, these variations, as well as variations in the subsequent reward prediction error response (159), conform to a single-peak probability distribution rather than amounting to categorical differences and distinct dopamine subpopulations. In addition to their continuous phasic response distribution, dopamine neurons are het-

erogeneous in most other anatomical, physiological, and neurochemical respects.

The initial activation component may reflect physical, motivational, and surprise salience and thus may enhance the impact of the prediction error response in reward learning compatible with associability learning rules (425, 336). In being highly sensitive to novelty, reward generalization, and rewarded contexts, this component may reflect an early assumption about the nature of an event that is novel, resembles a reward, or occurs within a generally rewarding context. Such events have a chance to be rewards and thus are potential rewards. In responding to such stimuli, dopamine neurons detect a maximal range of potentially rewarding events and objects. Through the very short latency of these responses, dopamine neurons detect these stimuli very rapidly, even before having identified their value, and can rapidly initiate neuronal processes for approach behavior. Once the stimulus has been identified and turns out not to be a reward, it is still time to alter neuronal processing and modify or halt behavioral reactions. If the stimulus is indeed a reward, precious time may be gained and the reward approached before anybody else without such a rapid detection system arrives. By overreacting and processing also potential rewards, the mechanism would prevent premature asymptotes in reward detection and minimize reward misses (avoiding "I do not move unless the reward is for sure"). Such a mechanism would be particularly important when sparse resources present challenges for survival. With early detection facilitating rapid behavioral reactions, the two-component nature of the phasic dopamine response results in better reward acquisition and thus provides competitive evolutionary advantages.

The phasic dopamine reward signal is only one manifestation of dopamine function in the brain. In addition to the distinct and slightly less phasic dopamine risk signal (see below), dopamine exerts a tonic enabling effect on postsynaptic neurons, whose function is considerably more heterogeneous than the rather stereotyped dopamine prediction error response, even when considering its initial detection component (518). Many of these tonic functions depend on the function of the brain structure influenced by tonic extracellular dopamine concentrations, as inferred from behavioral and neuronal alterations arising from inactivations, receptor agonist or antagonist applications, and polymorphisms. These functions extend from motor processes in the striatum evidenced by Parkinsonian movement deficits to prefrontal processes of working memory, attention, reversal learning, categorization, and response control (470). An active involvement of phasic dopamine signals in these vastly different functions is questionable, in particular for functions that are recovered by dopamine receptor agonists without reinstating phasic dopamine signaling. Parkinsonism does not result from deficient dopamine reward prediction error signaling. Thus dopamine function in the brain is vast and heterogeneous and extends well beyond the phasic dopamine reward signal. Serotonin has a similar tonic enabling function, which includes aversive and reward processes (100, 201, 481, 534, 635). The question "what is dopamine doing" reflects the initial idea of "one neurotransmitter-one function" that may originate from "one brain structure-one function." In view of the many different neuronal dopamine processes, a better question might be "what is the function of the specific dopamine process we are looking at." For the phasic dopamine signal, the answer seems to be bidirectional reward prediction error coding, with additional, slightly slower risk coding.

10. Dopamine responses during reward learning

During learning episodes, dopamine responses show gradual changes that reflect the evolution of prediction errors. Dopamine neurons acquire responses to reward-predicting stimuli (322) that transfer back to the first reward-predicting stimulus in longer task schedules (144, 521). Their activations disappear gradually with extinction (598), possibly due to inhibition from neighboring pars reticulata neurons activated during extinction (408). When learning several tasks in sequence, positive reward prediction errors are generated every time a reward occurs during initial trials but subside once rewards become predictable and performance approaches asymptote. Dopamine neurons show corresponding prediction-dependent reward responses during these periods **(FIGURE 13, *A* AND *B*)** (322, 521). A temporal difference model using dopamine-like prediction errors replicates well behavioral learning and performance in these tasks **(FIGURE 13*C*)** (573). During learning set performance with one rewarded and one unrewarded option, reward is initially predicted with $P = 0.5$. Chance selection of each option leads to positive and negative 0.5 prediction errors, respectively, and to corresponding phasic dopamine activations and depressions during initial learning trials (221). The error responses decrease with increasingly correct choices.

The transfer of dopamine activation from "unconditioned" reward to reward-predicting stimuli constitutes conditioning formalized by the Rescorla-Wagner and TD learning rules. Straightforward implementations of the TD model assume gradual TD error backpropagation via imaginary "internal" stimuli (374, 524). However, biological dopamine neurons do not show such gradual backpropagating responses (162) but transfer in single steps from reward to preceding actual stimuli and show simultaneous responses to both reward and stimuli with intermediate learning steps (410). Dopamine concentration transients in ventral striatum show similar transfer **(FIGURE 14*A*)** (117, 598). Biologically plausible TD implementations and spectral timing models achieve the single step response transfer to an earlier stimulus with stimulus and eligibility traces that mark recently active

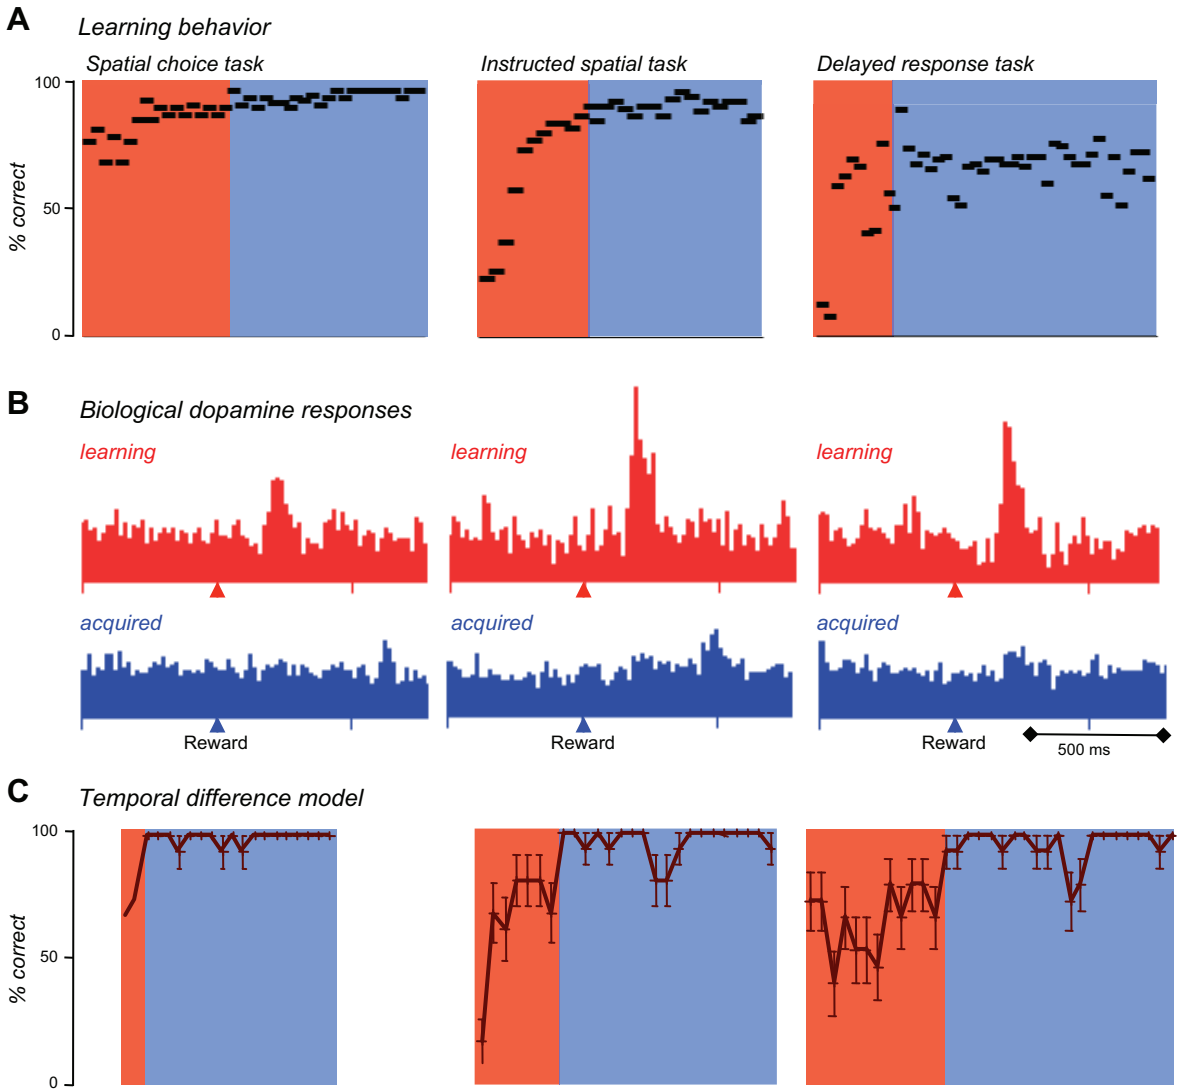

FIGURE 13. Dopamine prediction error responses reflect changing reward prediction during learning. *A:* stepwise learning of spatial delayed response task via intermediate spatial subtasks. Each dot shows mean percentage of correct behavioral performance in 20–30 trials during learning (red) and asymptotic performance (blue). *B:* positive dopamine reward prediction error responses during learning of each subtask, and their disappearance during acquired performance. Each histogram shows averaged responses from 10–35 monkey dopamine neurons recorded during the behavior shown in *A*. [*A* and *B* from Schultz et al. (521).] *C:* behavioral learning and performance of temporal difference model using the dopamine prediction error signals shown in *B*. The slower model learning compared with the animal's learning of the final delayed response task is due to a single step increase of delay from 1 to 3 s in the model, whereas the delay increased gradually in animals (*A*). [From Suri and Schultz (573), with permission from Elsevier.]

postsynaptic neurons for plasticity, as originally suggested **(FIGURE 14, *B–D*)** (71, 410, 573, 574). The eligibility traces may consist of intracellular calcium changes (154, 637), formation of calmodulin-dependent protein kinase II (236), IP_3 increase in dopamine neurons (203), and sustained neuronal activity in striatum and frontal cortex (522) reflecting previous events and choices in prefrontal neurons (30, 531). Thus use of eligibility traces results in good learning without small step backpropagation via imaginary stimuli (410, 573). These models account also better for the temporal sensitivity of prediction error responses (113, 573).

The acquisition of dopamine responses to conditioned stimuli enhances the strength of excitatory synapses onto dopamine neurons (568), and cocaine administration increases spike-time-dependent LTP in dopamine neurons (19, 318). In elucidating the mechanism, burst stimulation of dopamine neurons, mimicking dopamine reward responses, induces NMDA receptor-dependent LTP of synaptic responses in dopamine neurons (203). Compatible with the temporal characteristics of behavioral conditioning (423, 589), the burst needs to follow the synaptic stimulation by at least 0.5 or 1.0 s, whereas postsynaptic burst omission reverses LTP, and inverse timing induces long-term depres-

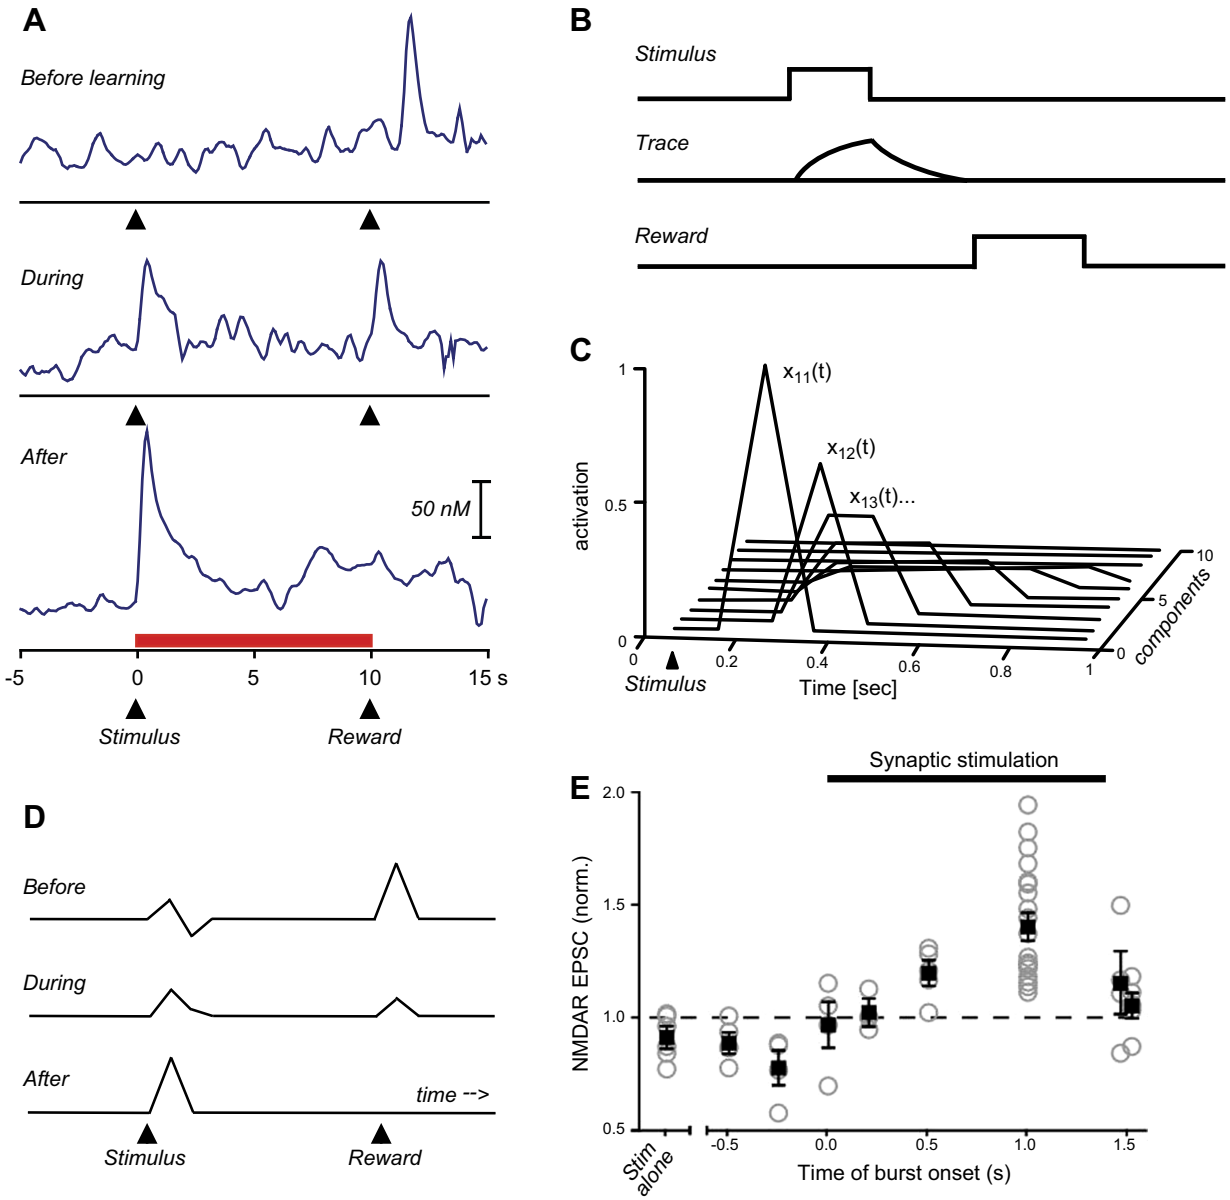

FIGURE 14. Plasticity of dopamine reward prediction error responses. *A:* transfer of dopamine response from primary reward to conditioned, reward-predicting stimulus during learning. The plots show voltammetrically measured dopamine concentration changes in ventral striatum of rats. Note simultaneous occurrence of responses to reward and stimulus during intermediate learning stage. [From Stuber et al. (598). Reprinted with permission from AAAS.] *B:* stimulus eligibility traces linking reward to stimulus during learning in original formulation of temporal difference model (TD) model. [Redrawn from Sutton and Barto (574).] *C:* stimulus eligibility traces used in biologically plausible implementation of TD model of dopamine prediction error responses. The traces allow single step transfer of dopamine prediction error signal from reward to an earlier stimulus. *D:* transfer of modeled dopamine prediction error response from reward to conditioned stimulus using eligibility traces shown in *B* and *C*. [*C* and *D* from Suri and Schultz (573), with permission from Elsevier.] *E:* time-sensitive plasticity of dopamine neurons in rat midbrain slices. LTP induction depends on timing of burst stimulation of dopamine neurons relative to their synaptic excitation. Only bursts occurring 0.5–1.5 s after synaptic stimulation lead to measurable LTP (excitatory postsynaptic currents, EPSC, mediated by NMDA receptors). [From Harnett et al. (203), with permission from Elsevier.]

sion **(FIGURE 14*E*)**. The 0.5- to 1.0-s delay is required to increase intracellular IP_3 as potential stimulus eligibility trace. Thus excitatory synapses onto dopamine neurons seem to mediate the acquisition of dopamine neurons to conditioned stimuli.

11. Non-dopamine prediction error signals

The colloquial meaning of error refers to incorrect motor performance. Climbing fibers of the cerebellum and neurons in superior colliculus and frontal and supplementary eye field

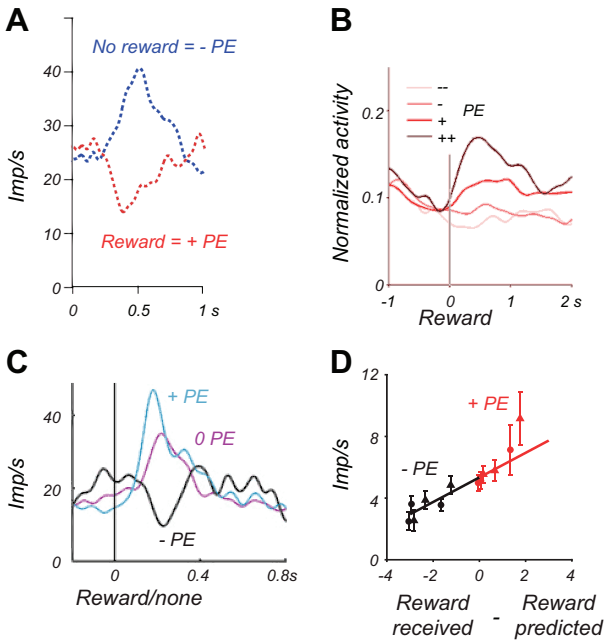

FIGURE 15. Bidirectional non-dopamine reward prediction error signals. *A:* averaged responses from 43 neurons in monkey lateral habenula during first trial of position-reward reversals. Reprinted with permission from Nature Publishing Group.] *B*: averaged responses from 8 neurons in rat striatum. Subjective reward values (tiny, small, large, huge) are estimated by a Rescorla-Wagner reinforcement model fit to behavioral choices. [From Kim et al. (275).] *C:* response of single neuron in monkey amygdala. [From Belova et al. (36), with permission from Elsevier.] *D*: response of single neuron in monkey supplementary eye field. [From So and Stuphorn (551).]

signal errors of arm or eye movements (182, 266, 278, 292, 395, 569, 607). Cerebellar circuits implement a Rescorla-Wagner type prediction error for aversive conditioning (273, 357). The identification of bidirectional dopamine error signaling extended neuronal error coding to reward.

Bidirectional reward prediction error signals occur in several brain structures. Lateral habenula neurons show bidirectional reward prediction error signals that are sign inverted to dopamine responses and may affect dopamine neurons via inhibitory neurons **(FIGURE 15*A*)** (344). Select groups of phasically and tonically firing neurons in the striatum and globus pallidus code positive and negative reward prediction errors bidirectionally **(FIGURE 15*B*)** (15, 134, 227, 275, 402). Some neurons in the amygdala display separate, bidirectional error coding for reward and punishment **(FIGURE 15*C*)** (36). In the cortex, select neurons in anterior cingulate (261, 531) and supplementary eye field **(FIGURE 15*D*)** (551) code reward prediction errors bidirectionally. The bidirectional reward prediction error responses in these subcortical and cortical neurons are straightforwardly appropriate for affecting plasticity at specific postsynaptic neurons for reinforcement learning.

Positive and negative components of reward prediction errors are also coded in select groups of non-dopamine reward neurons. Some neurons in the pedunculopontine nucleus are activated by both predicted and unpredicted rewards and by conditioned stimuli (136, 396, 410) but fail to show depressions to omitted rewards and thus process reward without producing a clear error signal (281). Pedunculopontine neurons with midbrain projections above substantia nigra show bidirectional error responses to reward versus no-reward-predicting cues, but only positive prediction error responses to the reward (228). Positive responses to unpredicted but not predicted rewards occur in norepinephrine neurons as part of their attentional sensitivity (22), and in nucleus basalis Meynert neurons (466). In the striatum, some phasically or tonically firing neurons are influenced by unpredicted reward delivery or unpredicted reward omission (21, 255, 275, 556). Some of these striatal responses are stronger in Pavlovian than operant tasks (17) or occur only after particular behavioral actions (556), suggesting selectivity for the kind of behavior that resulted in the reward. In the amygdala, some neurons are more activated by unpredicted than predicted rewards (36, 40) or show unidirectional, rectified activations with both unpredicted reward delivery and omission (475). In anterior cingulate and dorsolateral prefrontal cortex, activations induced by reward omission or erroneous task performance are known for >30 years (386). In some orbitofrontal neurons, unpredicted rewards outside of tasks elicit activations, whereas reward omission fails to elicit responses (602). Some neurons in anterior and posterior cingulate and supplementary eye field are activated by unpredicted delivery or omission of reward (11, 21, 246, 261, 354, 551) and by unpredicted positive or negative feedback provided by conditioned visual reinforcers (344). Unpredictedness enhances existing reward responses in anterior cingulate cortex (206). The unidirectional activations to unpredicted delivery or omission of reward may reflect surprise salience or rectified positive and negative reward prediction errors. In reflecting surprise salience, they may code the learning rate parameter α of attentional learning rules (425) according to *Equation 3* and serve to adjust the speed of learning (475).

12. Non-dopamine responses during reward learning

Tonically active striatal interneurons (TANs) acquire discriminant responses to reward-predicting auditory stimuli within 15 min of pairing with liquid, and lose these responses within 10 min of extinction (14). Neurons in rat striatum, orbitofrontal cortex, and amygdala acquire discriminatory responses to movement-instructing and reward-predicting visual, auditory, and olfactory stimuli during learning and reversal (253, 422, 512). The acquired responses are rapidly lost during extinction (29).

Repeated learning of new stimuli leads to learning set performance in which animals acquire novel stimuli within a few trials (202), thus allowing to record from single neurons

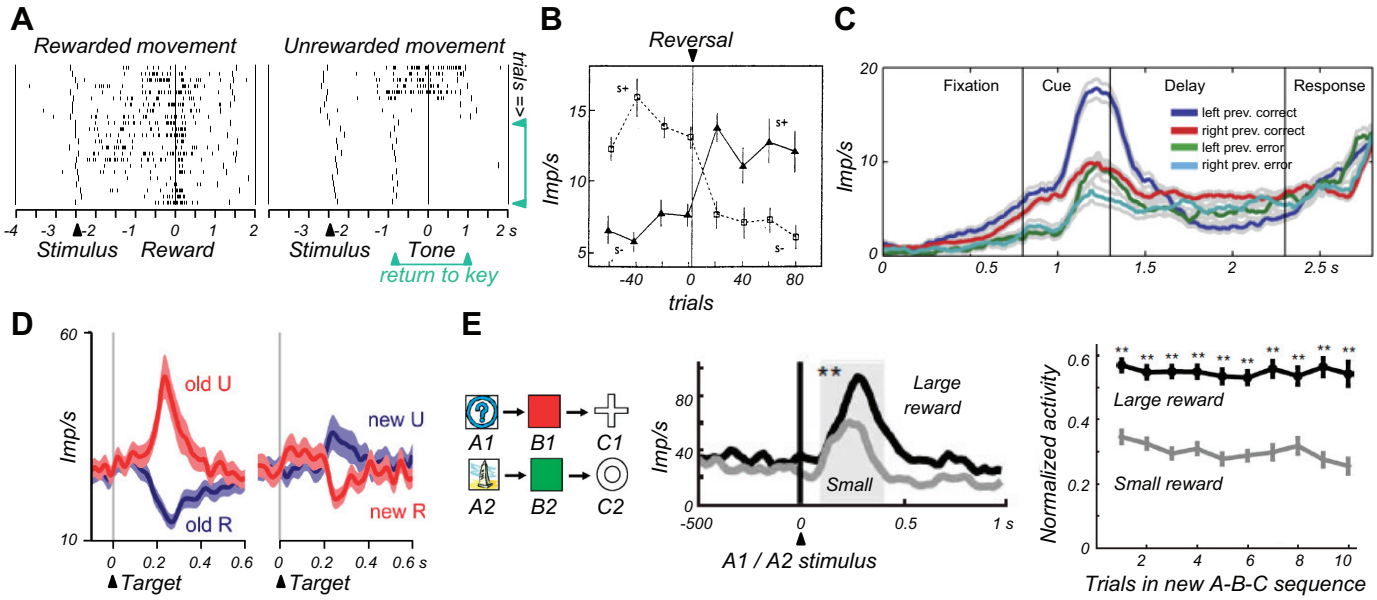

FIGURE 16. Overview of reward learning-related responses in monkey non-dopamine neurons. *A:* adaptation of reward expectation in single ventral striatum neuron during learning. In each learning episode, two new visual stimuli instruct a rewarded and an unrewarded arm movement, respectively, involving the acquisition of differential reward expectations for the same movement. Reward expectation is indicated by the return of the animal's hand to the resting key. This occurs with all rewarded movements after reward delivery (long vertical markers in left rasters, right to reward). With unrewarded movements, which alternate pseudorandomly with rewarded movement trials, the return occurs in initial trials after the tone (*top right*) but subsequently jumps before the tone (green arrows), indicating initial default reward expectation that disappears with learning. The reward expectation-related neuronal activity shows a similar development during learning (from *top* to *bottom*). [From Tremblay et al. (600).] *B*: rapid reversal of stimulus response in orbitofrontal neuron with reversed stimulus-reward association. S+ and S− are two different visual stimuli that are initially rewarded and unrewarded, respectivey. With reversal, they stay physically constant but inverse their reward prediction. [From Rolls et al. (485).] *C:* cue response in dorsolateral prefrontal cortex neuron reflecting correct, as opposed to erroneous, performance in previous trial in a delayed conditional motor task with reversal. This typical prefrontal neuron discriminates between left and right movements. Errors reduce differential left-right movement-related activity (previous trial correct: blue and red vs. error: green and blue). [From Histed et al. (217), with permission from Elsevier.] *D*: inference-related reversal of neuronal population responses in lateral habenula. These neurons are activated by unrewarded targets and depressed by rewarded targets. *Left*: in the first trial after target-reward reversal, before any new outcome occurs, the neurons continue to show activation to the old unrewarded target (red, old U) and depression to the old rewarded target (blue, old R). *Right*: in the second trial after reversal, after having experienced one outcome, the neuronal responses reflect the reward association of the other target. Thus the neurons are activated by the newly unrewarded target (blue, new U) and depressed by the newly rewarded target (red, new R), based entirely on inference from the outcome of only one target. [From Bromberg-Martin et al. (68).] *E:* inference of reward value from differentially rewarded paired associates in prefrontal cortex. Monkeys are first trained with two complete A-B-C sequences (*left*). Then, before the first trial of a new sequence, the two C stimuli are followed by large and small reward, respectively. For testing, the animal is presented with an A stimulus and choses the corresponding B and then C stimuli from the first new sequence trial on, even before sequential A-B-C-reward conditioning could occur. Neurons show corresponding reward differential activity (center, single neuron) from the first trial on (right, population average from 107 neurons), suggesting inference without explicit linking A and B stimuli to reward. [From Pan et al. (411). Reprinted with permission from Nature Publishing Group.]

during full learning episodes. Striatal and orbitofrontal neurons show three forms of reward related activity during learning (626, 600, 603, 639). Some neurons fail initially to respond to novel stimuli and acquire reward discriminatory responses during learning. Apparently they code valid reward predictions. To the opposite, other neurons respond initially indiscriminately to all novel stimuli and differentiate as learning advances, possibly reflecting exploration. A third group of neurons shows reward expectation activity that reflects an initial general expectation and becomes selective for rewarded trials as learning progresses **(FIGURE 16*A*)**. The increases in learning rate with electrical striatal stimulation suggest that some of these striatal neurons may mediate reward learning (639).

In analogy to learning set, repeated reversals of reward predictions of the same stimuli lead to reversal set performance in which animals switch after a single reversed trial

to the alternative option rather than requiring multiple learning trials, even without having experienced a reward. Prefrontal, orbitofrontal, and amygdala neurons show rapid response loss to previously learned stimuli and acquisition of the currently rewarded stimuli (626), closely corresponding to behavioral changes **(FIGURE 16*B*)** (422, 485). The changes occur several trials earlier in striatal neurons compared with prefrontal neurons (421), but are similar between orbitofrontal and amygdala neurons (378). Some striatal and cortical responses reflect the correct or incorrect performance of the previous trial in reversal sets, thus bridging information across consecutive trials **(FIGURE 16*C*)** (217).

Both learning sets and reversal sets define task structures and behavioral rules which allow individuals to infer reward values of stimuli without having actually experienced the new values. During reversals, responses in globus pallidus, lateral habenula, and dopamine neurons reflect the new reward value of a target already after the first reversed trial, based solely on inference from the other target **(FIGURE 16*D*)** (68). Neuronal responses in dorsolateral prefrontal cortex reflect reward value based on inference from paired associates **(FIGURE 16*E*)** (411) or transitivity (409). Neuronal responses in the striatum reflect inference by exclusion of alternative stimuli (409). These responses seem to incorporate the acquired rule into their responses, supposedly by accessing model-based learning mechanisms.

C. Dopamine Implementation of Reward Learning

1. Origin of reward prediction error response

The dopamine reward prediction error signal may derive from two basic mechanisms. The dopamine neurons may receive a complete bidirectional reward prediction error signal from presynaptic input. Alternatively, they may compute the signal from heterogeneous components by subtracting the predicted from the experienced reward at the time of the reward and, in the spirit of TD models, at the time of reward predictors. The computation would require separate inputs for positive and negative errors, both at the time of the final reward and at the time of cues predicting all future rewards.

Dopamine neurons receive main reward information from striatum, amygdala, subthalamic nucleus, pedunculopontine nucleus, rostromedial reticular nucleus, and GABAergic neurons of pars reticulata of substantia nigra (625). They receive homeostatic signals from lateral hypothalamus (464). However, dorsal, medial, and orbital prefrontal cortical areas in monkeys provide probably less direct inputs to dopamine neurons than often assumed (625) but could influence them transsynaptically via the striatum.

Bidirectional reward prediction error response components may arise from lateral habenula signals **(FIGURE 15*A*)** (344) which themselves derive from globus pallidus (227) but are sign inverted compared with dopamine responses. The habenula exerts strong and exclusively inhibitory influences on dopamine neurons (95, 250, 344) via GABAergic neurons in the rostromedial reticular nucleus (226, 249). The same habenula neurons show bidirectional punishment prediction error signals opposite to their reward prediction error responses. They respond to positive reward prediction errors in a very similar way as to negative punishment prediction errors (by depression), and to negative reward prediction errors similarly as to positive punishment prediction errors (by activation), thus coding value monotonically across rewards and punishers (346). However, it is unclear why the aversive habenula input would not impact on dopamine neurons (157, 160). Bidirectional reward prediction error inputs may also arise from select neurons in a number of other structures, including the striatum **(FIGURE 15*B*)** (15, 134, 275), amygdala **(FIGURE 15C)** (36), anterior cingulate (261, 531), and supplementary eye field **(FIGURE 15*D*)** (551). To make these neurons input candidates for the bidirectional dopamine prediction error signal would require demonstration of their projection to dopamine neurons, which may become technically possible by using selective optogenetic stimulation of error processing neurons that project to dopamine neurons.

Positive dopamine prediction error response components may arise from direct excitatory inputs from pedunculopontine neurons (131) responding to sensory stimuli, reward-predicting cues, and rewards (136, 228, 396, 410). In support of this possibility, inactivation of pedunculopontine neurons reduces dopamine stimulus responses (410). Norepinephrine neurons activated by attentional reward components (22) and nucleus basalis Meynert neurons activated by rewards (466) may also project to dopamine neurons. Different groups of striatal neurons exert activating influences on dopamine neurons via double inhibition (407) and respond to reward-predicting stimuli irrespective of the stimuli being themselves predicted (222) or incorporate reward predictions (17, 21, 255, 275, 402, 556). Positive response components may also derive from amygdala neurons that are activated by rewards irrespective of prediction (422), by unpredicted rewards (40), or by unpredicted reward delivery and omission (475). Reward responses in monkey frontal cortex (11, 21, 206, 246, 261, 347, 354) may reach dopamine neurons via the striatum.

Negative dopamine error responses may arise from GABAergic inputs from VTA, substantia nigra pars reticulata, or striatum (625). Some of these inputs are activated by aversive stimuli (10, 102, 582). Optogenetic activation of pars reticulata GABAergic neurons reduces dopamine impulse activity (613). Inhibition from GABAergic pars re-

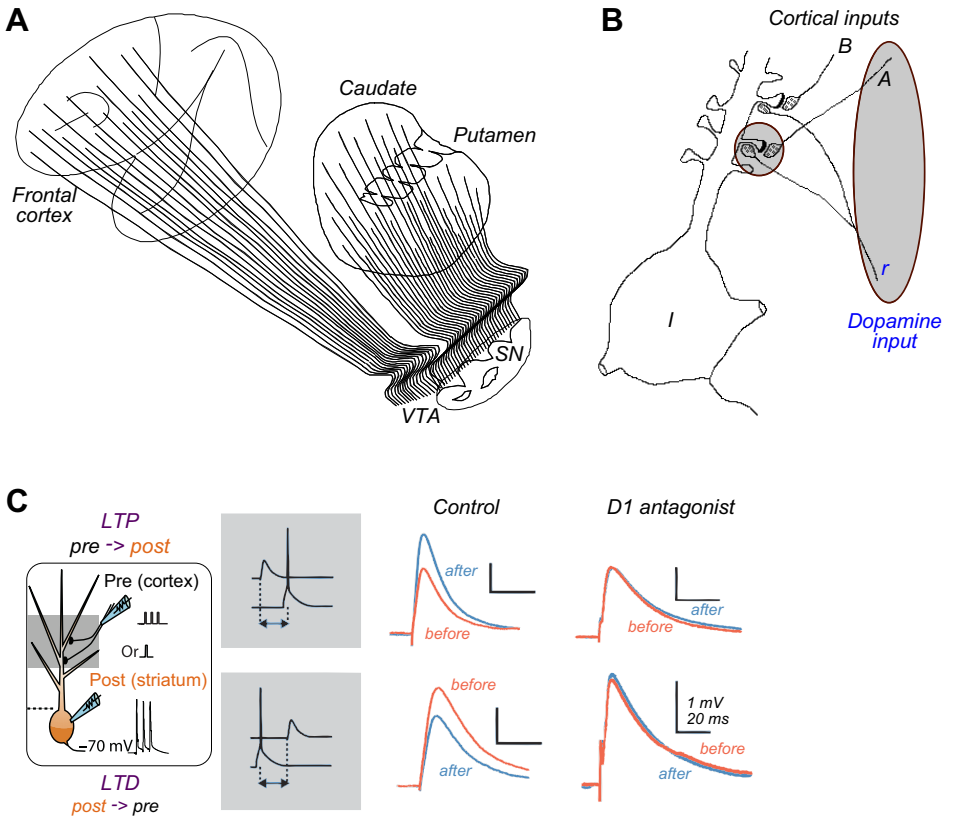

FIGURE 17. Anatomical and cellular dopamine influences on neuronal plasticity. *A:* global dopamine signal advancing to striatum and cortex. The population response of the majority of substantia nigra (SN) pars compacta and ventral tegmental area (VTA) dopamine neurons can be schematized as a synchronous, parallel volley of activity advancing at a velocity of 1–2 m/s (525) along the diverging projections from the midbrain to large populations of striatum (caudate and putamen) and cortex. [From Schultz (517).] *B:* differential influence of global dopamine signal on selectively active corticostriatal neurotransmission. The dopamine reinforcement signal (r) modifies conjointly active Hebbian synapses from active input (*A*) at striatal neuron (I) but leaves inactive synapses from inactive input (*B*) unchanged. Gray circle and ellipse indicate simultaneously active elements. There are ~10,000 cortical terminals and 1,000 dopamine varicosities on each striatal neuron (138, 192). Drawing based on data from Freund et al. (171) and Smith and Bolam (548). [From Schultz (520).] *C:* dopamine-dependent neuronal plasticity in striatal neurons. *Left*: experimental in vitro arrangement of cortical input stimulation and striatal neuron recording using a spike time dependent plasticity (STDP) protocol in rats. Control: positive STDP timing (striatal EPSP preceding action potential, Δt = 20 ms) results in long-term potentiation (LTP) (*top*), whereas negative STDP timing (striatal EPSP following action potential, Δt = −30 ms) results in long-term depression (LTD) (1, orange, and 2, blue, refer to before and after stimulation). Dopamine D1 recepor antagonist SCH23390 (10 μM) blocks both forms of plasticity, whereas D2 antagonist sulpiride (10 μM) has less clear effects and affects only plasticity onset times (not shown). [From Shen et al. (540). Reprinted with permission from AAAS. From Pawlak and Kerr (424).]

ticulata neurons showing sustained activations during reward prediction may also result in cancellation of reward activations in dopamine neurons by predicted rewards (102).

The computation of reward prediction error requires a reward prediction to be present at the time of the primary or higher order reward. This prediction may be mediated by the well-known sustained activations preceding rewards and reward-predicting stimuli in neurons of structures projecting mono- or polysynaptically to dopamine neurons, including orbitofrontal cortex (544, 602, 628), dorsal and ventral striatum (18, 205, 215, 523), and amygdala (40) (see below, **FIGURE 37, *D* AND *E***).

2. Postsynaptic influences

The phasic, time specific, reward prediction error reporting dopamine signal is propagated from specific dopamine populations in VTA and substantia nigra pars compacta (SNpc) to nucleus accumbens, dorsal striatum, frontal cortex, amygdala, and other forebrain structures. The widespread and diverging anatomical dopamine projections to postsynaptic structures show limited topography **(FIGURE 17*A*)** (177, 251, 342). Dopamine release and postsynaptic influence vary within small regions and are locally finely regulated (92). The tonic local dopamine concentration has separable, powerful enabling effects on a large variety of motor, cognitive, and motivational processes that are chal-

lenged by impaired dopamine function induced by Parkinson's disease, lesions, and psychopharmacological interventions (518). Distinction of the tonic function against the phasic signal is crucial for adequate conceptualization of dopamine's role in behavior. Importantly, interference of dopamine neurotransmission does not allow distinction between the two functions without special procedures. The deficits derive often from impaired tonic dopamine function and thus do not match the normal functions conveyed by phasic signals.

Dopamine synapses on dendritic spines of postsynaptic neurons in striatum and frontal cortex show a triad arrangement with cortical afferents that constitutes an architecture for three-factor Hebbian plasticity and allows the global dopamine reinforcement signal to exert differential influences on selectively active corticostriatal neurotransmission **(FIGURE 17*B*)** (171, 186, 461, 517). Indeed, electrical midbrain stimulation induces dopamine D1 receptor dependent long-term potentiation in striatal neurons in vivo (461) and expansion of cortical auditory fields for costimulated frequencies (28). Dopamine plays crucial roles in long-term potentiation (LTP) and depression (LTD) in striatum (82, 265, 294, 583), frontal cortex (194, 400), hippocampus (401), and amygdala (495). Dopamine turns tetanus stimulation-induced cortical LTD into LTP when paired with NMDA receptor activation (343). In spike-time-dependent plasticity (STDP) protocols, LTP occurs differentially when presynaptic stimulation precedes postsynaptic stimulation by a few tens of milliseconds, whereas LTD occurs with reverse sequence (48). Slice STDP protocols induce anatomical enlargement of striatal dendritic spines by burst-stimulating dopamine axons 0.3–2.0 s after depolarization of medium spiny striatal neurons, involving dopamine D1, but not D2, receptors and striatal NMDA receptors (642). The specific sequence of striatal excitation followed, but not preceded, by dopamine stimulation corresponds well to the temporal requirements for behavioral conditioning (423, 589). Correspondingly, dopamine D1 receptors are necessary for both LTP and LTD in striatal neurons, whereas D2 receptors may be more involved in the time course of plasticity **(FIGURE 17*C*)** (424). The effects may differ between striatal neuron types (540), as LTP in indirect pathway neurons does not depend on dopamine (294). In cultured hippocampus neurons, stimulation of dopamine D1 receptors enhances STDP LTP and turns LTD into LTP (648). These in vitro STDP data suggest a necessary role of dopamine in plasticity and should be carried to in vivo preparations for better functional assessment of their role in natural learning situations. Formal modeling demonstrates the suitability and power of dopamine-like reward prediction error signals in STDP learning (170, 247, 446), including prevention of run-away synaptic weights (375, 457).

3. Necessary dopamine involvement in learning (inactivation)

Hundreds of lesioning and psychopharmacological studies over the past 30 years demonstrate behavioral learning deficits with impaired dopamine function in a large variety of tasks. Following the three-factor Hebbian learning scheme (461, 517), intra-accumbens or systemically applied D1 receptor blockers or knockout of NMDA receptors on D1 receptor expressing striatal neurons impairs simple types of stimulus-reward learning **(FIGURE 18*A*)** (130, 163, 413). Similarly, intracortical D1 antagonist application impairs acquisition of differential neuronal responses in monkey prefrontal cortex and parallel behavioral learning in a delayed conditional motor task (440). Learning is somewhat less impaired by systemic D1 receptor blockade in tasks involving less direct reactions to stimuli and engaging less phasic dopamine responses (sign trackers versus goal trackers, **FIGURE 18*B***) (45, 163, 415). The learning deficits occur irrespective of performance deficits (163, 440, 624, 649, 650). Thus prediction error responses of dopamine neurons are not indiscriminately involved in all learning forms and

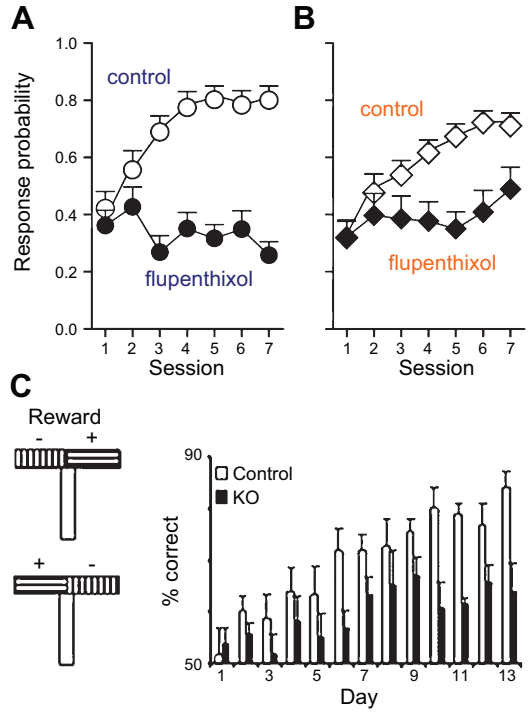

FIGURE 18. Differential learning impairment by dopamine receptor blockade. *A:* dopamine receptor blockade induces severe learning deficits in sign-tracking rats (learning under flupenthixol, not shown; test drug free, shown here). Sign trackers contact a conditioned stimulus before approaching the goal. *B:* dopamine receptor blockade by flupenthixol induces less severe learning deficits in goal-tracking rats. Goal trackers bypass the stimulus and directly approach the goal. [*A* and *B* from Flagel et al. (163). [From Zweifel et al. (650).]

play more important roles when prediction errors have more direct effects.

Genetic NMDA receptor knockout on mice dopamine neurons reduces neuronal burst responses to reward-predicting stimuli and, in parallel, induce deficits in a wide range of learning situations including conditioned place preference, maze learning, and operant conditioning **(FIGURE 18*C*)** (624, 649, 650). Correspondingly, $GABA_A$ receptor knockout on dopamine neurons enhances dopamine release and T-maze and lever press learning (414). Without permitting adaptation during ontogenetic development, inactivation of dopamine neurons by local muscimol impairs learning from unexpected reward increase or omission (478). Transient direct or transsynaptic optogenetic inhibition of dopamine neurons induces place dispreference learning in choices between two compartments (see **FIGURE 19*E*** below) (244, 582).

Taken together, learning depends on intact dopamine function in simple reward contiguity situations with explicit, easily identifiable rewards and conditioned stimuli that engage phasic dopamine responses. Learning may not depend on dopamine neurons in situations in which they do not show phasic responses. Learning may also occur despite dopamine impairments when other learning systems compensate within the employed time frames, which may consist of switching to other struc-

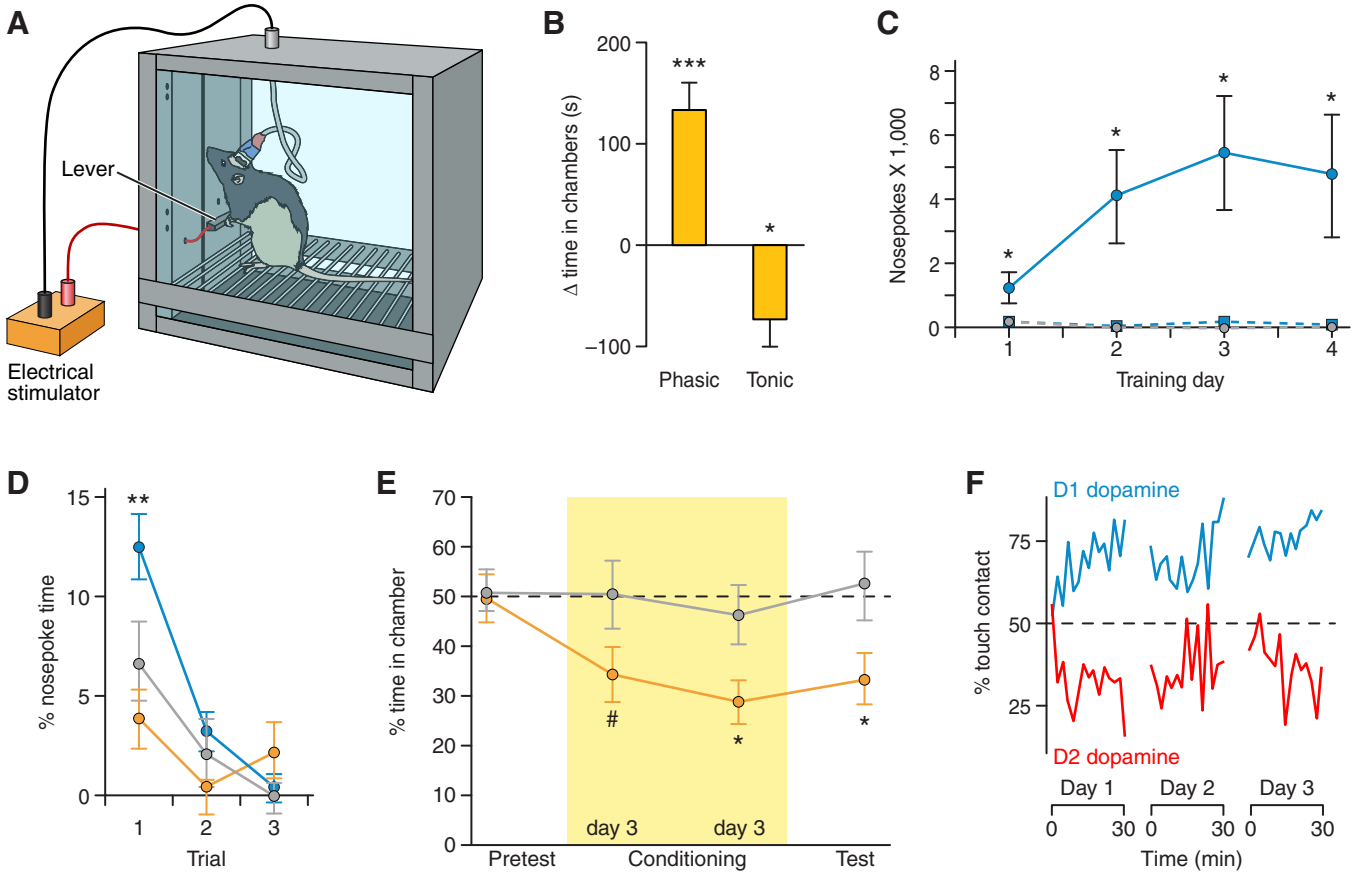

FIGURE 19. Effects of dopamine stimulation on behavioral learning. *A:* operant self-stimulation chamber. Pressing the lever elicits an electrical or optogenetic stimulus delivered to a specific brain structure through an implanted electrode/optrode. [From Rentato M. E. Sabatini, The history of electrical stimulation of the brain, available at http://www.cerebromente.org.br/n18/history/stimulation_i.htm.] *B:* place preference conditioning by phasic but not tonic optogenetic activation of dopamine neurons in mice. [From Witten et al. (641), with permission from Elsevier.] *D:* optogenetic activation of dopamine neurons unblocks learning of visual stimulus for nosepoke in rats, as shown by stronger response to stimulus paired with optogenetic stimulation in a blocking procedure (blue) compared with unpaired stimulus (orange) and stimulation in wild-type animals (gray). Response decrements are typical for unreinforced tests ("in extinction"). [From Steinberg et al. (562). Reprinted with permission from Nature Publishing Group.] *E:* place dispreference conditioning by direct optogenetic inhibition of dopamine neurons in mice (yellow; optical stimulation alone, gray). [From Tan et al. (582), with permission from Elsevier.] *F:* operant conditioning of approach (blue) and avoidance (red) behavior by optogenetic activation of D1 and D2 dopamine receptor expressing striatal neurons, respectively, in mice. [From Kravitz et al. (293). Reprinted by permission of Nature Publishing Group.]

tures after receptor blockade or lesions or altering ontogenetic development in gene knockouts. Fine-grained behavioral analysis may nevertheless reveal subtle remaining learning deficits. Given the crucial importance of reward for survival, multiple, flexible systems that sustain basic forms of learning despite partial impairments are biologically plausible and would enhance evolutionary fitness.

4. Sufficient dopamine involvement in learning (stimulation)

Intracranial electrical self-stimulation (398) induces operant learning of lever pressing **(FIGURE 19*A*)**. The effect is partly based on activation of VTA and SNpc dopamine neurons (103, 155) and involves dopamine release onto D1 receptors in nucleus accumbens (117). Optogenetic activation of midbrain dopamine neurons in rodents elicits learning of place preference, nose poking and lever pressing, and restores learning in a blocking procedure **(FIGURE 19, *B–D*)** (2, 244, 271, 562, 605, 641). Optogenetically induced nose poke learning occurs also with activation of dopamine axons in rat nucleus accumbens and is attenuated by intra-accumbens infusion of dopamine D1 and D2 receptor antagonists, suggesting involvement of dopamine projections to nucleus accumbens (562). The stimulations are similar in frequency to natural dopamine activations (20–50 Hz) but often exceed their natural durations of 150–250 ms by 2–7 times (500-1,000 ms), although stimulation durations of 200 ms are also effective (271, 641). The longer-than-natural activations induce more dopamine release in vitro (641) but may be compromised by the limited capacity of dopamine neurons for prolonged discharges due to pronounced tendency for depolarization block (54, 463). In contrast to 50-Hz phasic optogenetic dopamine activation, tonic (1 Hz) stimulation does not induce place preference learning (605), emphasizing the efficacy of phasic activations. In monkeys, electrical 200 Hz/200 ms VTA microstimulation induces choice preferences and neuromagnetic striatal activations, presumably reflecting dopamine activations (20). Opposite to excitations of dopamine neurons, direct optogenetic inhibition of dopamine neurons, or their indirect inhibition via activation of local, presynaptic GABA neurons, leads to place dispreference learning **(FIGURE 19*E*)** (244, 582). Conceivably the optogenetic excitation and inhibition of dopamine neurons mimic positive and negative dopamine prediction error signals and affect learning accordingly.

Learning induced by stimulation of dopamine neurons and their postsynaptic targets demonstrates the acquisition of associations with stimulation reward rather than simply reflecting arousal, response bias, direct effects on behavior, or performance enhancement, as the learned behavior is retained over several days, declines only gradually during extinction (271, 293, 582, 605) and is sensitive to devaluation by contingency degradation (641). The learning may involve striatal dopamine receptors, as optogenetic stimulation of D1 receptor expressing striatal neurons induces approach learning and stimulation of D2 receptor containing striatal neurons induces avoidance learning **(FIGURE 19*F*)** (293). The dichotomous striatal functions go back to learning models showing choice preference mediated by D1, and dispreference by D2, receptor containing striatal neurons and their respectively associated direct and indirect pathways (169). Taken together, electrical and optogenetic activation of dopamine neurons seem to mimic the natural dopamine prediction error responses to rewards and elicit learning behavior. The wider question is, to which extent would dopamine responses to a natural reward bias Pavlovian associations with that reward or operantly condition actions leading to the reward?

IV. APPROACH AND CHOICE

Rewards induce approach behavior and serve as arguments for economic choices. These functions involve a fundamental requirement, the prediction of reward that elicits reward expectation. We can approach an object because we expect it to be a reward. Without that expectation, we would approach an unknown object only when we are exploring the world. The same holds for choices. Final outcomes are often not apparent at the time of choices. Without such information, choices would be guesses and thus be very inefficient. One simply cannot make informed decisions without knowing what to expect from each option. Explorations are not informed choices but are helpful for detecting potentially better rewards. Thusgoal-directed approach behavior and informed choices are based on predictions of reward.

Predictions are acquired in the most basic form by Pavlovian conditioning. The sound of the bell predicts the sausage to Pavlov's dog. Also, the stimuli occurring during operant conditioning become Pavlovian conditioned reward predictors as the improving behavior results in more rewards. Each stimulus may become a higher order reward through conditioning and learning and thus has distinct economic value. Money does not have homeostatic or reproductive functions on its own but allows individuals to acquire nutritional and mating rewards and thus is a non-primary reward. More complex forms of prediction learning involve observation of other individuals, inference of events based on acquired knowledge, as in Bayesian updating in which the "posterior" probability of event occurrence arises from the "prior" probability, and conditional and reflective reasoning ("if I do this I can expect to obtain that reward"). In mediating Pavlovian and operant conditioning, in addition to stimulus-reward and action-reward pairing, the three-term contingency under which a discriminative stimulus signals an effective action-reward relationship constitutes the key factor for goal-directed approach behavior and informed choices. Contingency requires prediction errors, which serve to acquire and update the crucial predictions. Reward neurons are sensitive to contingency **(FIGURE 5)** (41) and code reward prediction errors **(FIGURE 7)** (517).

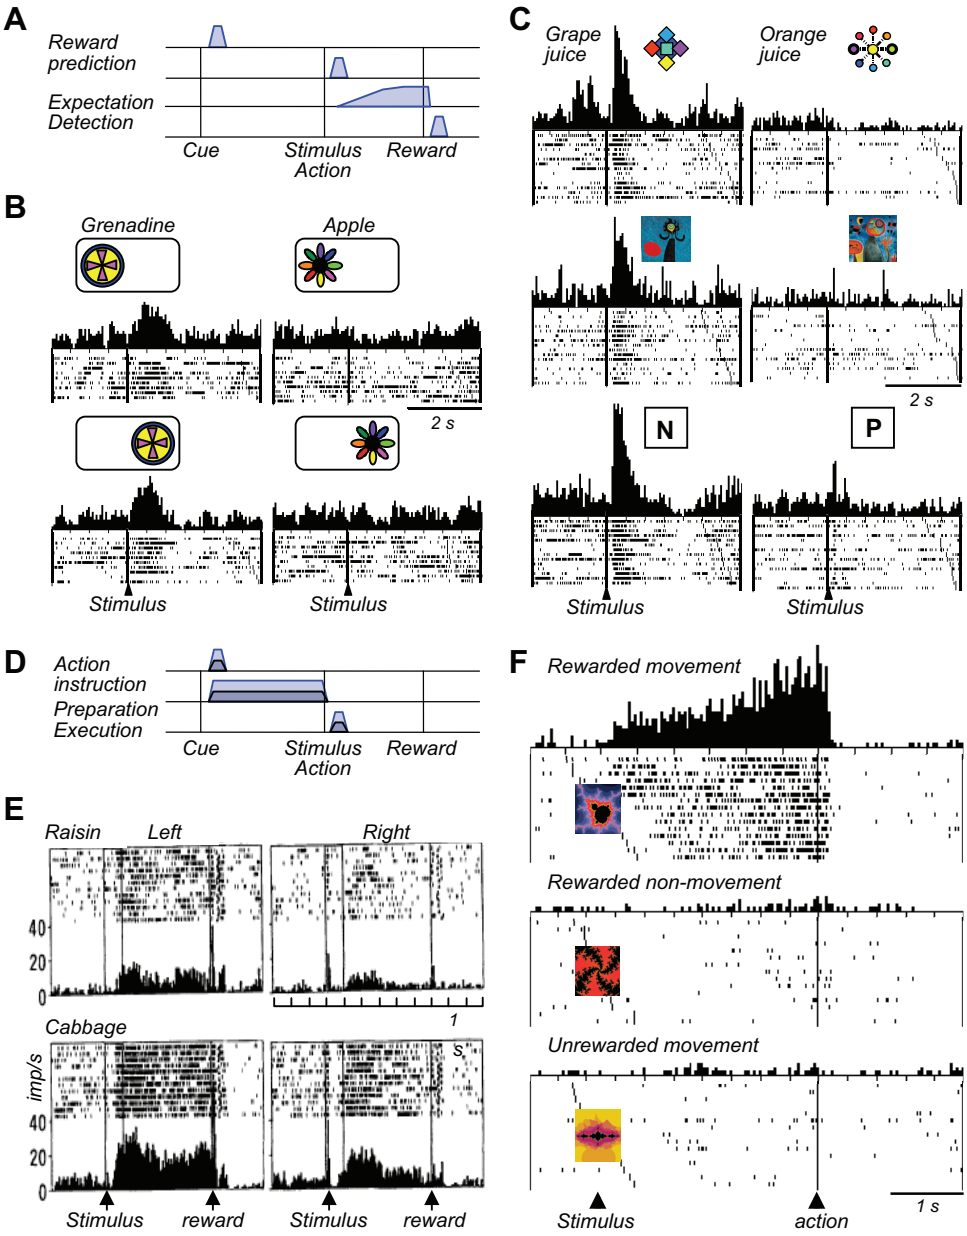

FIGURE 20. Explicit and conjoint neuronal reward signals in monkeys. *A:* scheme of explicit reward processing. Reward-predicting responses occur to an initial cue or to an action-inducing stimulus. Anticipatory activity occurs during the expectation of reward elicited by an external stimulus or action. Reward detection responses occur to the final reward. These different activities occur in separate neurons, except for dopamine neurons which all show similar responses (and no sustained reward expectation activations). *B:* neuronal reward processing irrespective of spatial position in orbitofrontal cortex. Differential activation by conditioned stimulus predicting grenadine juice but not apple juice, irrespective of spatial stimulus position and required movement (spatial delayed response task). *C:* neuronal reward processing irrespective of visual stimulus features in orbitofrontal cortex. Differential activations by conditioned stimuli predicting grape juice but not orange juice, irrespective of visual stimulus features. [*A* and *B* from Tremblay and Schultz (601).] *D:* scheme of conjoint reward-action processing. Predicted reward affects neuronal activity differentiating between different movement parameters during the instruction, preparation, and execution of action (e.g., spatial or go-nogo, blue vs. gray). *E:* conjoint processing of reward type (raisin vs. cabbage) and differentiating between spatial target positions in dorsolateral prefrontal cortex (spatial delayed response task). Reprinted with permission from Nature Publishing Group.] *F:* conjoint processing of reward (vs. no reward) and movement (vs. no movement) in caudate nucleus (delayed go-nogo task). The neuronal activities in *E* and *F* reflect the specific future reward together with the specific action required to obtain that reward. [From Hollerman et al. (222).]

A. Basic Reward Processing

1. Events eliciting reward responses

Explicit neuronal reward signals code only reward information. They occur as phasic responses to the delivery of "unconditioned" rewards, as phasic responses to conditioned, reward-predicting stimuli, and as sustained activity during the expectation of reward **(FIGURE 20A)**. They reflect only reward properties and do not vary with sensory or motor aspects **(FIGURE 20, *B* AND *C*)**.

"Unconditioned" liquid or food rewards elicit explicit reward signals in all main components of the brain's reward system (see **FIGURES 7**; **8, *A–C***; **13*B***; **AND 27*A***) (16, 18, 42, 60, 205, 215, 322, 383, 387, 405, 422, 451, 492, 541, 592). Reward responses are found also in premotor, prefrontal, cingulate, insular, and perirhinal cortex (8, 246, 369, 569). Some prefrontal neurons code the reward of the preceding trial (30, 179).

Conditioned, reward-predicting stimuli induce phasic explicit reward signals in all main reward structures of the brain, including orbitofrontal cortex, striatum, amygdala, and dopamine neurons (VTA and SNpc) (**FIGURE 20, *B* AND *C***; see also **FIGURES 5*B***; **7*C***; **8*C***; **9, *A*, *B*, AND *D***; **27, *B* AND *D***) (e.g., Refs. 41, 205, 276, 319, 371, 387, 405, 422, 516, 542, 601). These responses occur irrespective of the physical properties of the conditioned stimuli. Similar reward-related stimulus responses occur also in dorsolateral prefrontal cortex and anterior insula (338, 369, 411).

During reward expectations evoked by reward-predicting stimuli, select neurons in orbitofrontal cortex, striatum, and amygdala show slower, sustained explicit reward signals (see **FIGURES 16*A* AND 38, *D* AND *E***) (18, 37, 215, 601) which may also reflect reward timing (528) and temporal reward structure (40).

In addition to inducing explicit reward signals, rewards affect existing sensory-specific and action-specific activity. Neurons coding reward together with differential sensory information are found in orbitofrontal, dorsolateral prefrontal, perirhinal, and inferotemporal cortex (231, 319, 371, 394, 411). Reward affects neuronal activity differentiating between different movement parameters during the instruction, preparation and execution of action in prefrontal and premotor cortex **(FIGURE 20, *D* AND *E*)** (135, 282, 313, 348, 476, 606, 627), anterior and posterior cingulate cortex (354, 542), parietal cortex (381, 427, 433), striatum **(FIGURE 20*F*)** (107, 205, 222, 260, 308), globus pallidus (178), substantia nigra pars reticulata (502), superior colliculus (243), and amygdala (428). By processing information about the forthcoming reward during the preparation or execution of action, these activities may reflect a representation of the reward before and during the movement toward the reward, which fulfills a crucial requirement for goal-directed behavior (133). However, in motor structures, increased movement-related activity with larger rewards may reflect the more energized movements rather than representing a true conjoint reward-action signal (476). After reward delivery, responses in dorsolateral prefrontal neurons differentiate between movement directions (606).

Taken together, reward neurons show passive responses to reward-predicting stimuli and rewards, and sustained activities in advance of predicted rewards. Explicit reward signals in a limited number of brain structures reflect reward information but code neither sensory nor motor information. In contrast, sensory and motor neurons in several brain structures process reward information conjointly with sensory responses and action activity **(FIGURE 21)**. Reward coding involves the large majority of dopamine neurons, which all respond in a very similar manner to the effective events. In contrast, only specific and much smaller fractions of neurons in the other reward structures show reward activity, and their responses can be quite selective for one or the other of several task events.

2. Subjective reward perception

Neuronal reward responses may depend on the subjective perception of reward-predicting stimuli. In a signal detection task, monkeys correctly or incorrectly report the presence of stimuli (hit and false alarm, respectively), and correctly or incorrectly report stimulus absence (correct rejection and miss) (122). Dopamine neurons are activated by an initial task stimulus only when the animal correctly reports its detection, whereas they are not activated by the same physical stimulus when the animal reports its absence (miss). Thus subjective perception of the stimulus is necessary to activate dopamine neurons. However, subjective perception is not sufficient, as dopamine neurons do not respond when the physically absent stimulus is incorrectly reported as present (false alarm) **(FIGURE 22)**. The prediction error responses to a subsequent cue and to the final reward reflect also the subjective perception of the initial

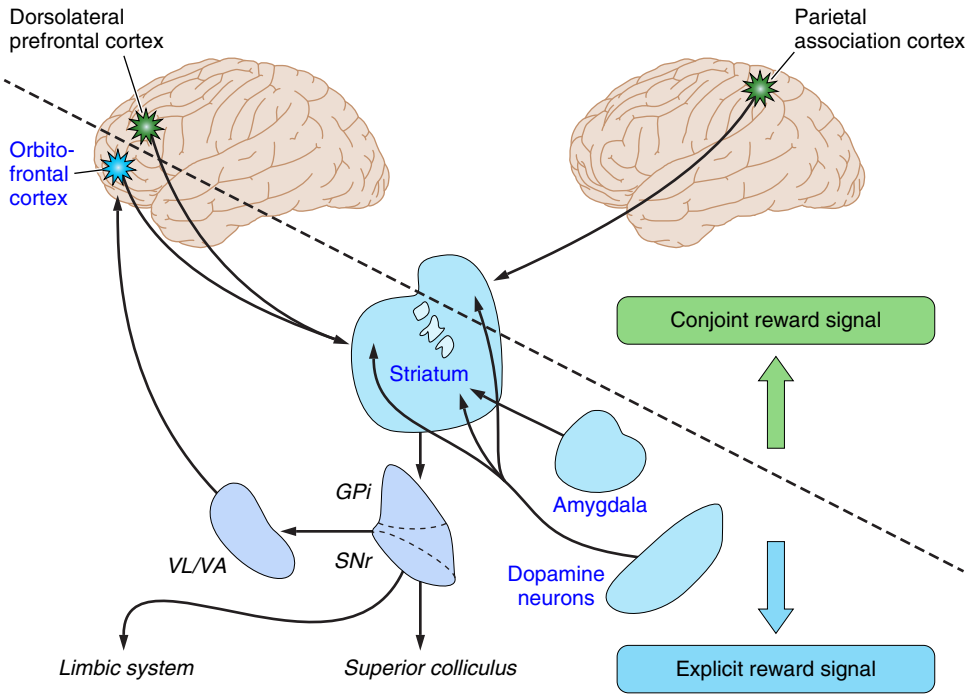

FIGURE 21. Simplified scheme of brain structures and connections involved in explicit and conjoint reward processing. The diagonal line schematically separates brain structures with neurons processing explicit reward information from structures whose neurons process reward together with sensory or action information. The striatum contains both classes.

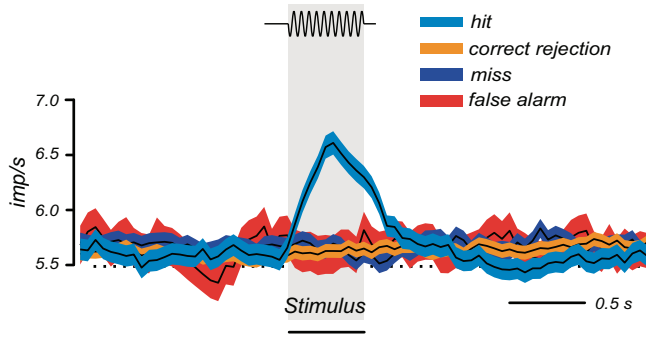

FIGURE 22. Dopamine reward response requires correct perception of reward-predicting stimulus. The reward prediction error response occurs only when the stimulus is present and is correctly reported as being present (hit; vibratory stimulus, *top*) but not when the stimulus is missed (miss) or is absent but incorrectly reported as present (false alarm). [From de Lafuente and Romo (122).]

stimulus. The responses are lower, and thus incorporate the prediction from the initial stimulus, when the animal had accurately reported stimulus presence compared with inaccurately reporting stimulus absence, even though the stimulus was physically the same. Thus dopamine responses reflect the animal's subjective perception and valuation of reward-predicting stimuli beyond their purely physical properties.

3. Distinction to unrewarding events

Reward neurons differentiate reward against neutral and aversive events. Dopamine neurons code reward but are not activated by aversive stimulus components **(FIGURE 11)** (157, 159, 160), even though their initial event detection response covaries with physical salience, novelty salience, stimulus generalization, and reward context **(FIGURE 10)**. In contrast, neurons in other reward structures respond selectively to aversive stimuli. Non-dopamine VTA neurons are activated by airpuffs and footshocks (102, 582). Some amygdala neurons are activated by airpuffs and conditioned stimuli predicting airpuffs, separately from reward neurons (422). Neurons in nucleus accumbens are differentially activated by sucrose or quinine, including their predictive stimuli (484). Neurons in orbitofrontal and anterior cingulate cortex, and TANs in striatum, respond differentially to aversive airpuffs, reward liquids, and their predictive stimuli and follow reversal between punishment and reward (10, 255, 452, 592). In dorsolateral prefrontal cortex, more neurons respond to reward than airpuff (283) and are differentially activated by gains or losses of reward tokens (532). In medial prefrontal cortex, dorsal neurons respond more frequently to air puffs, whereas ventral neurons are more sensitive to liquid reward (372). Thus punishment responses are often well separated from reward processing.

Some reward neurons respond also to punishers and thus process the motivational salience common to both reinforcers rather than reward or punishment separately. These reinforcer neurons are seen in amygdala (387), dorsolateral prefrontal cortex (283), and parietal cortex (309). In contrast to separate monotonic variations with reward and punishment magnitude, salience responses peak with high reward and high punishment and thus follow a U function (309). Thus restricted populations of reward neurons fail to discriminate against punishers and thus code motivational salience.

However, there is a caveat when interpreting the results of studies using aversive stimuli for probing negative motivational value. As indicated for dopamine responses above, it is crucial to distinguish between the physical impact of the stimulus and its motivational aversiveness. However, most studies apply presumably aversive stimuli without assessing their aversiveness to the individual animal. A good method to do so in neurophysiological studies is to estimate the negative value quantitatively on a common currency basis, using psychophysical choice procedures against rewards **(FIGURE 11*A*)** (160). Even substantial airpuffs are surprisingly not reported by the animals as having negative reward value (160).

B. Reward Value

1. Central role of subjective reward value

The ultimate function of reward is evolutionary fitness, which requires us to survive and reproduce. Thus rewards have survival value that is specific for us, and thus subjective. "Subjective" does not refer to conscious awareness but simply to the own person. Our brain detects the rewards that are necessary for this function. It is not really important what the objective, physical amount of a reward is, and often not even possible to know, as long as the reward provides us with the best chance for survival and reproduction. If we have plenty of food, a bit more does not matter much, but if we are starving, even a small amount is important. We do not necessarily go for the largest reward if it does not mean anything for us. We go for the reward that most satisfies our needs at that moment. A rat normally readily does not drink a salt solution but will do so when it is deprived of salt (472). Striving for the highest subjective value is built into our behavior by evolutionary selection. If we do not choose the highest value, we are at a disadvantage and over time fall behind and ultimately lose out against competitors that get better values. The striving for subjective value might also explain why we sometimes make choices that others do not understand. They are good for us at the moment, because we make them based on our own, private, subjective values, irrespective of whether we are consciously aware of them or not. Subjective valuation is also mechanistically reasonable. Reward function in individuals is defined by behavior driven by the brain, and the brain has evolved for our individual survival and reproduction rather than for an impersonal cause. We can identify all

substances in a wine and add up their prices from a catalog, but as a chemist and not as a wine connoisseur who is trying to maximize the personal pleasure based on subjective taste preferences. It is not the chemists's impersonal cause directed at the physical molecules but the wine connoisseur's subjective pleasure that contributes to fitness (by providing relaxation and encouraging taste discrimination training).

2. Assessing subjective value from behavior

Although subjective value is the key variable underlying approach and choices, it is a theoretical construct and not an objective measure. Utilitarianism aimed to achieve the greatest happiness for the greatest number of people (39). This might be assessed by an external person with honorable intentions (the benevolent dictator), by a hypothetical hedonimeter that measures happiness (142), or by subjective ratings (for example as "experienced utility") (259). However, benevolent dictators are implausible, hedonimeters are technically difficult, and ratings are subjective. Furthermore, there is no way of comparing subjective values between individuals because we cannot compare their feelings or, as a famous economist put it, "You cannot feel how much my tooth aches." In contrast, behavioral reactions and choices are measurable. They are often described in terms of preferences. However, preferences are internal private states and therefore prone to misjudgement and misreport. To operationalize preferences and remove their metaphysical and emotional connotations of purpose, desire, and pleasure, Samuelson (501) coined the term *revealed preferences* that are elicited by choices and follow specific axioms, notably consistency and transitivity. Thus choices elicit private and unobservable preferences hidden deep inside us and make them measurable as utility in an objective way. Other, more loosely defined, terms for value include survival value (survival of individuals or genes, referring to the reward function in evolutionary fitness), motivational or incentive value (eliciting approach behavior), and affective value (linking reward to emotion). There will be a more specific definition of economic utility further down with neuronal value signals.

There are several mechanisms for inferring subjective value from approach behavior and choices. In approach behavior, reward value is revealed by the speed (e.g., reaction time), duration, intensity, frequency, accuracy (e.g., error rate), and persistence of behavioral reactions. The reward eliciting the strongest approach behavior presumably has the highest "value." In choices, reward value is revealed by the probability of choosing one option over all other alternatives. The reward being consistently selected is considered to have the highest subjective value (assuming "rational" choices). In animals, psychophysical assessment of choices provides good measures for value. In humans, auction mechanisms allow to assess the subjective value of goods (willingness to pay). Thus approach and choices reveal the unobservable variable of value. When I see someone move faster towards an object or choose the object over another one, I get the intuitive notion that the object must have a higher value for the person. Value becomes simply a shortcut term denoting the impact of a reward on measurable behavioral choices. To avoid the circular definition when using value for explaining behavior we say that individuals behave "as if" they are maximizing value. Deducing the variable of value from behavior allows us to search for neuronal value signals for approach and choices. Such neuronal value signals would provide a physical basis for the theoretical notion of value and thus inform and validate economic choice theory.

3. Relative choices and common currency value

Behavioral choices reflect the values of choice options relative to each other. They will remain stable irrespective of value variations as long as the relative values of the options remain unchanged. For example, doubling of all option values should not affect choices. Thus value can only be expressed relative to other options within a given set of options. We can define a common reference reward, compare behavioral choices between that reference reward and any other reward, and thus establish a common value ranking or numeric scale defined by the reference reward which then serves as common currency. Money is a good example. It assesses the value of any reward in common monetary units. Any reward can be used as common currency for rewards differing in type, magnitude, probability, risk, delay, and other attributes. Just as different physical objects are measured on common scales of length or weight, different rewards can be measured on a common scale of value. Note that the common scale is only valid for an individual decision maker and does not provide a common measure to all decision makers. One dollar, or any other common currency, may constitute a different value for you than for me.

How can we choose between apples and oranges? We can compare the sensory properties of different objects using standardized scales of physical and chemical measures. As reward value is not a physical but a behavioral measure, this does not help. Rather, we should assess the values of such incommensurable rewards relative to each other. The idea of common currency allows us to quantify value relative to a unique reference that quantifies the value of rewards with vastly different properties. The activity of orbitofrontal and dopamine neurons reflects the subjective, common currency value integrated from different liquid rewards in close correspondence to behavioral choices (405) and extends to food rewards (301) **(FIGURE 23)**, suggesting a physical basis for the theoretical notion of common currency. Common currency is a necessary and sufficient feature of value coding, as it reflects independence from sensory properties and follows the idea of a reward retina as earliest neuronal detector of value (519).

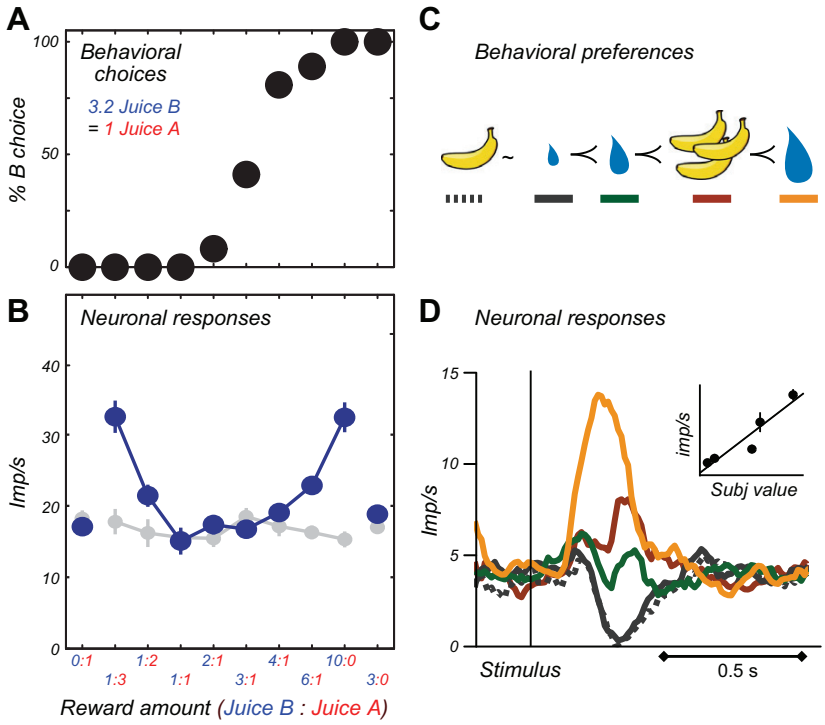

FIGURE 23. Common currency coding of subjective value derived from different rewards in monkeys. *A:* behavioral choices between two juice rewards of varying amounts reveal common scale subjective economic value. Amounts at choice indifference (50% choice of either reward) reveal 3.2 times lower value of reward B than reward A (which serves as common scale reference). *B:* common currency coding of subjective value derived from different juice rewards in single orbitofrontal neuron. Response to reward-predicting stimulus increases with amount of either juice, irrespective of juice. This activity codes the decision variable of chosen value. [*A* and *B* from Padoa-Schioppa and Assad (405). Reprinted by permission from Nature Publishing Group.] *C:* rank ordered, ordinal behavioral preferences for different liquid and food rewards, as assessed in behavioral choices between blackcurrant juice (blue drop) and mashed mixture of banana, chocolate, and hazelnut food (yellow bananas). ~, indifferent; <, preferred. *D:* common currency coding of subjective value in dopamine neurons (averages from 20 neurons). Colors refer to the rewards shown in *C*. [*C* and *D* from Lak et al. (301).]

Relative values do not always correlate with choices. Decision makers have a tendency to select the highest option unproportionally more often than its relative value against other options. Such maximizing choices favor the highest valued option irrespective of value variations as long as the ordinal value ranking among the options remains unchanged. Maximizing is reduced during exploratory behavior, when individuals occasionally check an inferior option for potential improvement, but exploration declines with increasingly stable values. These mechanisms are captured by the "temperature" parameter of the softmax function that models choices (333, 575). Exploration, modeled by higher temperature, may lead to effective decorrelation between choice probability and value and reveal serious constraints on the computation of value from choices. However, specific test methods control for these possible misreadings, including assessment of indifference points (subjective equivalence between choice options) in psychophysical procedures.

4. Value in natural rewards

Natural rewards, for which reward processing has evolved, contain nutrients and other substances of survival value. These rewards, like foods and drinks, have sensory properties, like shape, color, texture, viscosity, taste, and smell that help to detect, identify, and distinguish the reward objects. However, the sensory properties do not have nutrient value. Approach behavior and choices maximize reward value, not sensory properties. The transfer from sensory properties to value involves experiencing the value of the object, associating that value with the object's sensory properties using Pavlovian and higher forms of learning, and then using the predicted value for approach and choices. Thus sensory discrimination serves to identify the object via sensory receptors rather than determining its value. The sensory-value distinction lies at the core of reward processing; the sensory properties belong to the external object, whereas the reward properties derive from internal brain function attributing value to external objects.

Reward neurons distinguish between the sensory and value attributes of rewards. Amygdala and dopamine neurons show faster sensory and slower value responses (160, 422). Orbitofrontal and amygdala neurons follow reversed value associations of physically unchanged stimuli (422, 485). Orbitofrontal and striatal reward neurons discriminate between different food and liquid rewards but are insensitive to their visual and spatial attributes (205, 405, 601). Satiation on particular rewards reduces reward value responses in orbitofrontal and ventromedial prefrontal cortex (58, 105) but leaves sensory responses in primary gustatory cortex unaffected (487). Salt depletion induces reward responses in ventral pallidum to physically unchanged salt solutions (591). Thus the intuitive distinction between sensory and value attributes of rewards has a neurophysiological basis.

5. Non-value factors in choices

Besides being based on positive and negative economic value (gain and loss and their corresponding emotions) and exploration, real life economic choices are also determined by other factors. The factors include strategy, heuristics,

personal history, peer example, social pressure, conventions, traditions, prejudice, idiosyncrasies, morals, ethics, culture, religion, superstition, nationalism, chauvinism, daily irrationalities, and many others. Some originate from experiences that maximized gains and minimized losses and then led to automatisms that are no longer questioned for economic value. (Note that such automatisms are distinct from habits which may develop from goal-directed behavior and are based on value.) Other choice factors have evolved without explicit understanding of distant gains. Just as birds do not know the partial differential equations describing the coordination of their movements, individuals engage in behaviors without understanding why they do them, how they do them, and what the benefits are. These automatisms have evolved through evolution and provide guidance of behavior to varying but often large extents. Their advantages are transmission of beneficial behavioral traits, but their possible disadvantages are inconsistencies and domination by higher values during choices. Decisions based on automatisms would involve brain processes related to schemata and models of behavior, rules, emotions, social memory, theory of mind, and other cognitive functions.

The impact of automatisms should be considered in relation to value as key variable for economic choices. The true character of most automatisms differs fundamentally from that of gains and losses, and decision makers may not compute economic values when following habitual strategies or conventions. Then deriving value from economic choices would be very difficult and needs to be restricted to specific situations in which the automatism component can be estimated. This is often difficult and may easily lead to inconsistent choices when different situations engage different automatisms. What is truly missing is a definition of value independent of choice behavior. A neuronal value signal might provide such a measure and allow interpretations of economic choices. For example, a neuronal value signal identified independently of a particular choice situation might help to assess the contribution of value in choices in which automatisms also play a role.

C. Construction of Neuronal Value Signals

1. Value functions

Intuitively, the value of a reward increases monotonically with its physical magnitude. A larger drop of juice is worth more than a smaller drop, except when satiation results in asymptotic and then decreasing value and thus breaks monotonicity (see below). The value of a reward depends also on the frequency of its occurrence which is modeled as probability. Stimuli that predict more likely rewards are valued higher. Given their occurrence with specific magnitudes and probabilities, rewards constitute probability distributions of individual reward magnitudes, and choices between two rewards can be viewed as choices between probability distributions (417). The first statistical moment in probability distributions is the expected value (EV), which constitutes the sum of probability-weighted magnitudes (first moment of probability distributions)

$$\mathrm{EV} = \sum_i [m_i * p_i(m_i)]; \text{ over all } i \qquad (8)$$

with m as magnitude (objective property of good), p as objective probability, and i as individual reward occurrences. The mean of increasingly large samples approaches the EV.

Probability is a theoretical construct that is derived from the measured frequency of event occurrence. Probability theory, as developed by Pascal and Fermat, allowed transferring the measure of experienced event frequency into the predictive measure of probability. For biological agents and their neurons, this transfer requires learning and memory, as the frequency of events impinging on sensory receptors needs to be counted in relation to other events and expressed as probability. The fact that there are no sensory receptors for probability strengthens the notion of a theoretical construct. Thus probability assessments mediate the transition from reacting to individual events to predicting future event occurrence. The past experience of reward frequency is registered by neurons and, true to the nature of predictions, processed to predict rewards and guide future behavior. By presenting events with a given frequency to animals, we assume that this transfer takes place, and we can search for neuronal activity that reflects reward probabilities. As described above with Pavlovian conditioning, the activity is necessarily predictive of the overall frequency of reward occurrence and thus reflects the reward value of the predictive stimulus. Thus the brain reacts to and assesses the frequency of individual rewards and transfers this measure into predictive activity reflecting the probability of future rewards.

The intuition of subjective value underlying economic choices combines with the failure to explain human choices by EV (43) and led to the axiomatic formulation of Expected Utility Theory (504, 617), which defines expected utility as a measure of subjective value in analogy to *Equation 8* as

$$\mathrm{EU} = \sum_i [\mathrm{u}(m_i) * p_i(m_i)]; \text{ over all } i \qquad (9)$$

with u(m) as (subjective) utility. The main utility functions are power, logarithmic, exponential, and quadratic as well as their combinations (295), which can model human choices adequately (225). Logarithmic utility may combine the logarithmic Weber function that describes the sensory impact of reward objects with a logarithmic valuation function of objective, physical reward magnitude and probability.

Utility is a hypothetical variable reflecting the subjective preferences elicited by behavioral choices. Whereas objective, physical value is measurable directly in milliliters or grams, utility is not measurable directly but inferred from behavioral choices (and maximized by decision makers). Thus the only physical measure from which utility can be inferred is behavioral choices. Choices are the tool to assess utility, and choices are the key method that economists accept for this assessment. There is a crucial difference between subjective value and utility. Although both subjective value and utility are estimated from measured behavioral choices, utility is a mathematical function of objective value [u(m)] that allows to predict the subjective value even for choices that have not been measured. Such mathematical functions allow to determine whole distributions of subjective values and establish useful terms such as EU for comparison between choice options. Utility is a universal measure of subjective value that does not require immediate behavioral assessment every time and thus constitutes the fundamental variable of economic decision theory.

The curvature of utility functions reflects marginal utility. Marginal utility is defined as the increment in utility gained from one additional unit of consumption, or the decrement from one unit less consumption, which is mathematically the first derivative of the utility function. Progressively decreasing marginal utility leads to concave functions (downward concave, as viewed from below, decreasing first derivative), which models the decreasing welfare one derives from ever more reward **(FIGURE 24A)**. A "well-behaved" economic utility function is concave, continuous, monotonically increasing, and nonsaturating (295, 341). It is based on money of which apparently one cannot get enough. Utility functions vary between different rewards, different risk levels (631), and different individuals. Utility functions for other rewards, like foods and drinks, do saturate and may even decrease, as too much food or liquid may become aversive and thus have negative marginal utility, effectively destroying monotonicity of the utility function **(FIGURE 24B)**. The "bliss point" is the utility producing maximal satisfaction. In contrast, increasing marginal utility leads to convex functions **(FIGURE 24C)**, suggesting that wins in high ranges are considered more important than the same gains in lower ranges ("small change"). In some cases, gains are valued increasingly more but ultimately become less important, leading to an initially convex and then concave utility function (173, 339) **(FIGURE 24D)**. Effectively, all combinations of curvatures of utility functions are possible, but the typical, "well-behaved" concave utility function is the standard model in economics.

The subjective weighting of value extends to reward probability. In particular, low and high probabilities are often distorted. Prospect Theory refines *Equation 9* to

$$\mathrm{EU} = \sum_i \{\mathrm{u}(m_i) * \pi[p_i(m_i)]\}; \text{ over all } i \qquad (10)$$

with π as probability weighting function (and P replacing EU in popular notation) (258) (Prospect Theory in addition incorporates references, different curvatures, and different slopes for losses than gains). The probability weighting function $\pi(p)$ is most nonlinear at $0.0 < P < \sim 0.2$ and $\sim 0.5 < P < 1.0$ and can be modeled with a one- or two-parameter function (α) (435) with an inflection point $\pi(p) = p$ at about $P = 0.37$, or a linear-in-log-odds function (187) in which gamma reflects curvature (low = inverted S, high = regular S) and α reflects elevation. Low probabilities can be distorted by a factor of 10,000. Well-trained monkeys show similar nonlinear, inverted S-shape probability weighting as humans with similar inflections points around $P = 0.37$ **(FIGURE 25)** (559).

Given that rewards affect behavior primarily through their subjective value, and that utility u(m) constitutes the central subjective reward function in economics, we can use *Equations 9* and *10* to state reinforcement learning *Equations 1*, *2*, *4*, and *5* in terms of economic utility

$$\mathrm{UPE}(t) = \lambda(t) - \mathrm{EU}(t) \qquad (10A)$$

$$\mathrm{EU}(t+1) = \mathrm{EU}(t) + \alpha * \mathrm{UPE}(t) \qquad (10B)$$

$$\mathrm{UTDPE}(t) = \left[\lambda(t) + \gamma \sum \mathrm{EU}(t)\right] - \mathrm{EU}(t-1) \qquad (10C)$$

$$\mathrm{EU}(t+1) = \mathrm{EU}(t) + \alpha * \mathrm{UTDPE}(t) \qquad (10D)$$

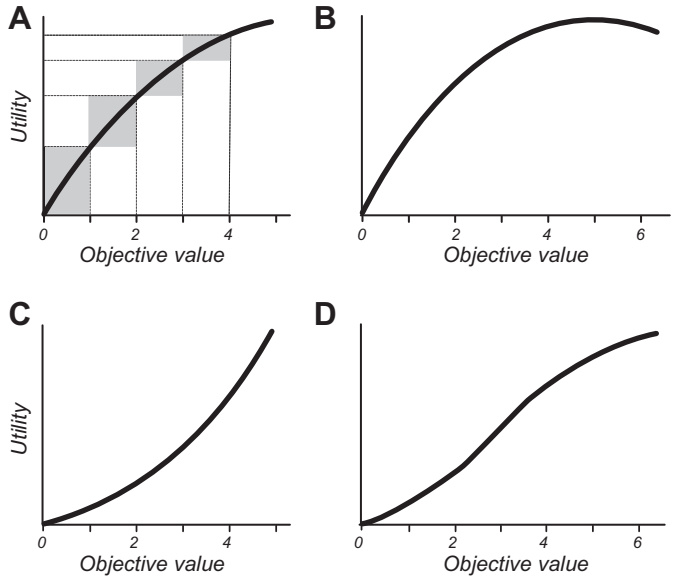

FIGURE 24. Utility functions. *A:* a "well behaved," gradually flattening ("concave"), continuous, monotonically increasing, nonsaturating utility function, typically for money. Gray rectangles indicate decreasing marginal utility (*y*-axis) with increasing wealth despite identical changes in objective value (*x*-axis). *B:* a saturating, nonmonotonic utility function typical for many biological rewards. Marginal utility becomes negative when an additional unit of consumption reduces utility (right end of function). *C:* a convex utility function, with gradually increasing marginal utility. *D:* a convex-concave utility function typical for progressively increasing marginal utility in lower ranges and progressively decreasing marginal utility in higher ranges.

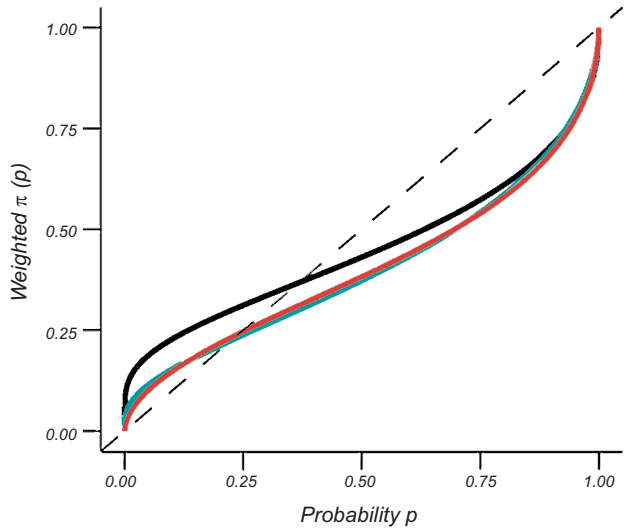

FIGURE 25. Nonlinear reward probability weighting functions estimated from behavioral choices in monkey. Fitting by one-parameter Prelec function (435) (black), two-parameter Prelec function (green), and linear-in-log-odds function (red) (187, 305). [From Stauffer et al. (565).]

Note that λ refers to the utility u(m) of the actual single reward received, whereas EU derives from the statistical utility distribution. Thus the utility prediction errors UPE(t) and UTDPE(t) constitute the key reinforcement terms for decision variables defined by economic utility.

Economists distinguish three principal forms of utility. First, scalar utility is subjective value as a mathematical function of physical, objective value. Utility can be derived from marginal utility under risk (to result in cardinal utility) or from the marginal rate of substitution without risk (amounting to ordinal utility). Cardinal utility functions established by choices under risk (617) provide a quantitative, numeric, mathematical characterization of the preference structure (257). Cardinal utility is valid up to positive affine transformations ($y = ax + b$) and can be psychophysically estimated from certainty equivalents at choice indifference between certain and risky options, starting at the distribution ends and advancing centrally by iteration (fractile or chaining procedure) (87). Cardinal utility can be expressed as u(m) (*Equation 9*) and is a requirement for establishing neuronal utility functions as neuronal signals have cardinal characteristics. In contrast, ordinal utility provides only a rank order of utilities and indicates whether a good is better or worse than another, without indicating on a numeric scale how much better or worse it is. It is only of limited value for establishing neuronal correlates of economic utility (higher versus lower neuronal responses for better or worse goods without numeric scaling). The marginal rate of substitution indicates the amount of good A a consumer is willing to give up to obtain one unit of good B while maintaining the same utility. The "distance" between curves of constant utility (indifference curves) indicates at least ordinal utility. Second, mean-variance utility is derived from objective value and risk via Taylor series expansion (see below, *Equations 21* and *21A*). Third, prospect theory extends utility by incorporating probability distortion (**FIGURE 25 AND** *Equation 10*), different loss than gain slopes (see below **FIGURE 29*E***) and reference dependency (see below **FIGURE 32** and *Equation 22A*).

The term of utility derives from the original utilitarian philosophers (39, 363). In economic decision theory, utility is defined by formal axioms (504, 617) that postulate how individuals behave in a meaningful manner "as if" they were maximizing utility. The term of utility is often used for convenience without requiring formal axiomatic tests in every instance (150, 324). This article follows this tradition, although that usage should not discourage axiomatic testing when identifying neuronal utility signals. Thus economic utility is a specific form of subjective value, which is derived from objective behavioral measures in individuals (but not across individuals). Utility has stricter requirements than subjective value by assuming an underlying, usually nonlinear, mathematical function that derives utility from objective value [u(m), as used in *Equation 9*]. If assessed from risky choices, utility is unique up to a positive affine transformation, which defines a cardinal function.

2. Neuronal value coding

The definition of cardinal, quantitative, numeric utility is important for investigating neuronal utility signals. The prime neuronal signal that is communicated to other neurons is the action potential. With sensory information, the signal arises from dedicated receptors whose stimulation induces numeric neuronal signals. Its strength as a signal is quantitatively expressed as firing rate (impulses/s) (3) and, to some extent, as pattern of action potentials. Firing rate is quasi-continuous between 0 and 1,000 impulses/s within the usual periods of 10–60 min of data sampling and usually increases or decreases monotonically with the phenomenon it codes. The same neuronal processing principles could be used for coding reward utility. For such neuronal signals to approach a meaningful mathematical function of utility, utility needs to be cardinal. It would be incorrect to derive a cardinal neuronal function from ordinal utility. This requirement would not apply if one would only look for ordinal higher firing rate for a higher (or lower) ranked, ordinal reward. With these characteristics, neuronal utility signals are physical (hardware) manifestations of a hypothetical variable that can only be inferred from behavioral choices. Although choices are the key method for assessing utility from behavior, utility neurons should also reflect utility at the time of reward reception, as this is the most important event for the survival of the organism.

Reward magnitude exerts a physical impact on sensory receptors. Reward magnitudes induce monotonically graded responses in dopamine neurons and in neurons in the stria-

tum, amygdala, and orbitofrontal, ventrolateral prefrontal, dorsolateral prefrontal, cingulate and posterior parietal cortex (12, 42, 107, 205, 262, 313, 354, 381, 405, 433, 598, 620). For rewards that do not vary in physical impact, like money, magnitude coding needs to be explained by other mechanisms including Pavlovian and cognitive processes.

Stimuli predicting specific reward probabilities induce graded responses in dopamine, striatum, and posterior parietal neurons and also in orbital, ventromedial, ventrolateral, dorsolateral, and cingulate prefrontal neurons, along with graded behavioral reactions and choices (12, 15, 17, 161, 261, 262, 354, 372, 376, 381, 402, 418, 433, 500). The transfer of dopamine responses from rewards to reward-predicting stimuli **(FIGURES 7*C* AND 14, *A* AND *D*)** may constitute a suitable correlate for the transition from reporting experienced reward frequency to coding reward probability. There are no neurophysiological studies on probability distortions. Human neuroimaging has shown probability distortions of values analogous to *Equation 10* (241, 595) but no behavioral distortions with valueless probabilities (110). Thus reward neurons transform the theoretical construct of probability into another theoretical construct called value (both of which are measurable from behavioral choices).

Increasing EVs induce graded neuronal responses in dopamine, striatum, orbitofrontal, ventromedial prefrontal, ventrolateral prefrontal, dorsolateral prefrontal, cingulate, and posterior parietal cortex neurons **(FIGURE 26)** (12, 261, 262, 354, 381, 402, 433, 418, 500, 598). In addition to characterizing reward coding, these data suggest a general biological basis for the mathematical constructs of EV, for which there are no sensory receptors. However, it is unlikely that these neurons code objective EV specifically rather than the subjective value that is monotonically related to objective value. Nevertheless, neuroscience applauds to the genius of the earlier mathematicians postulating biologically implemented theoretical terms.

Appropriate behavioral tests reveal that reward neurons typically code subjective value. Reward responses in orbitofrontal cortex, ventromedial prefrontal cortex, parietal cortex, striatum, globus pallidus, amygdala, lateral habenula and dopamine neurons closely reflect subjective behavioral choices **(FIGURE 23)** (301, 405, 433). Subjective value coding is also evident in specific situations, including satiation or deprivation without physical reward changes (58, 105, 591), differently delayed conditioned reinforcers (66, 67), temporal discounting of reward value (see below **FIGURE 28*D***) (79, 158, 285, 477, 479), and adaptation to identical reward magnitudes (see below **FIGURE 33, *A* AND *B***) (42, 284, 332, 403, 601). Details will be presented in the following sections.

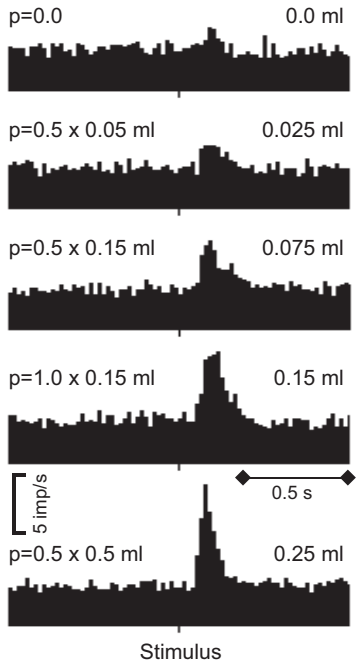

FIGURE 26. Neuronal value coding by monkey dopamine neurons. Monotonically increasing responses to increasing expected value (EV), irrespective of individual probability-magnitude combinations. EVs (*right*) are from 5 binary probability distributions with different probabilities and magnitudes of juice reward indicated at *left*. Population average from 55 dopamine neurons. Note that these responses do not suggest specific coding of EV as opposed to expected utility (EU), as at the time this distinction was not made experimentally. [From Tobler et al. (598).]

Although subjective value coding confirms the close behavioral-neuronal relationships of reward processing, it is agnostic about the relationship to physical reward value. In contrast, economic utility defines this relationship mathematically. Neuronal correlates of utility are found in dopamine neurons (560). Utility functions in monkeys may transition from convex via linear to concave with increasing reward volumes **(FIGURES 24*D* AND 27*A*)**, which reflects nonmonotonic marginal utility (first derivative of utility) and results in nonmonotonic utility prediction errors. This utility profile is closely paralleled by nonmonotonically changing dopamine prediction error responses with gambles placed at different parts of the utility function **(FIGURE 27*B*)**. With unpredicted rewards eliciting positive prediction errors, dopamine responses increase monotonically **(FIGURE 27*C*)** and thus follow the monotonic increase in utility prediction error (Δu) but not the nonmonotonic variation in marginal utility ($\Delta u/\Delta x$ or du/dx). Thus the dopamine reward prediction error response constitutes a utility prediction error signal that reflects marginal utilty but does not explicitly code marginal utility. Marginal utility relates well to prediction error, as both terms conceptualize deviations from a reference (prediction and current wealth, respectively).

Given its coding of utility, the dopamine signal can be stated as

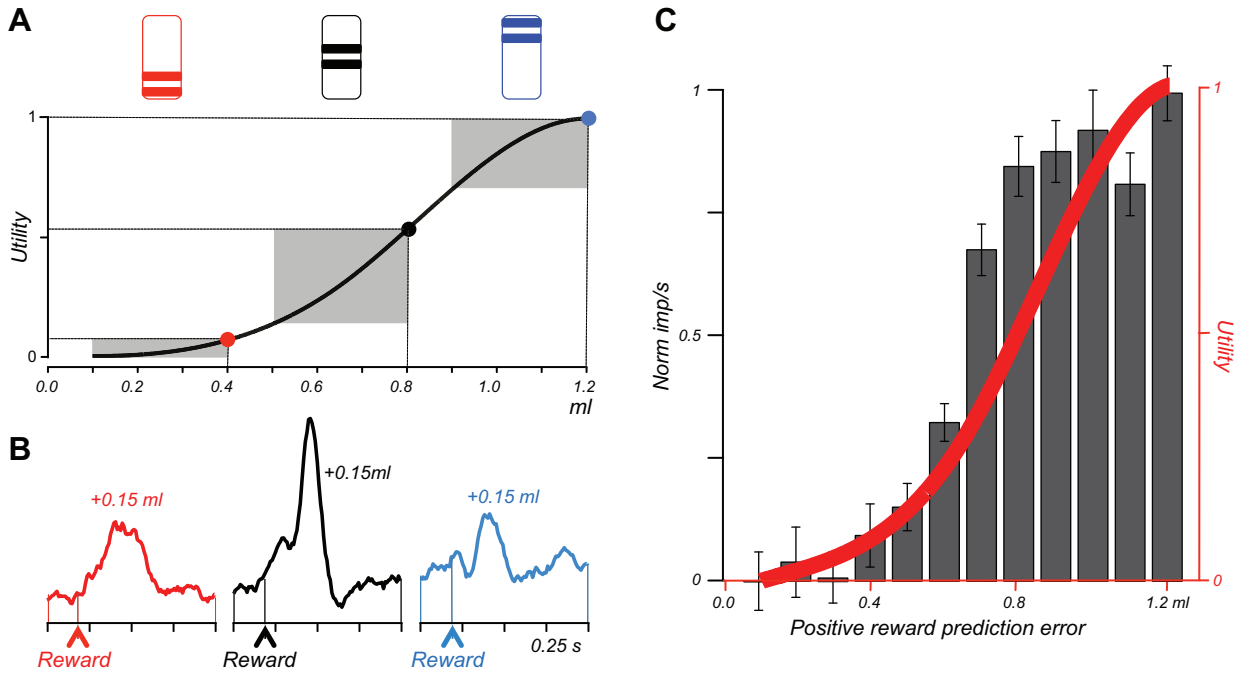

FIGURE 27. Utility prediction error signal in monkey dopamine neurons. *A*, *top*: gambles used for testing (0.1–0.4; 0.5–0.8; 0.9–1.2 ml juice; $P = 0.5$ each outcome). Height of each bar indicates juice volume. *Bottom*: behavioral utility function in monkey. Delivery of higher reward in each gamble generates identical positive physical prediction errors across gambles (0.15 ml, red, black, and blue dots). Due to different positions on the convex-concave utility function, the same physical prediction errors vary nonmonotonically in utility. Shaded areas indicate physical volumes (horizontal) and utilities (vertical) of tested gambles. *B:* positive neuronal utility prediction error responses (averaged from 52 dopamine neurons) to higher gamble outcomes in same animal (colored dots on utility function in *A*). The nonmonotonically varying dopamine responses reflect the nonmonotonically varying first derivative of the utility function (marginal utility). *C:* positive utility prediction error responses to unpredicted juice rewards. Red: utility function. Black: corresponding, nonlinear increase of population response ($n = 14$ dopamine neurons) in same animal. [*A–C* from Stauffer et al. (560).]

$$\text{DaResp}(t) \sim \text{UPE}(t) \qquad (10E)$$

and formulated for temporal difference (TD) utility error

$$\text{DaResp}(t) \sim \text{UTDPE}(t) \qquad (10F)$$

and can be fully expressed by using *Equations 6* and *7*, replacing V by EU and applying *Equations 10A* and *10E*

$$\text{DaResp}(t) \sim \lambda(t) - \text{EU}(t) \qquad (10G)$$

$$\text{DaResp}(t) \sim \left[\lambda(t) + \gamma\sum\text{EU}(t)\right] - \text{EU}(t-1) \qquad (10H)$$

As some neurons in other reward structures code also reward prediction errors, DaResp in *Equations 10E* through *10H* may be replaced by error signals from such neurons if their utility coding were established in future experiments.

As utility is not simply a measure of subjective value but derives mathematically from objective reward measures, utility coding extends the dopamine response well beyond subjective reward value coding seen with multiple rewards, effort cost, and risk (116, 156, 301, 570). Utility as higher specification of the dopamine response likely applies also to multiple rewards, effort cost, and risk whose neuronal coding is so far characterized only as subjective value (risk is already incorporated into the utility response in **FIGURE 27*B***).

3. Motivational state

Based on the intuition that the primary function of nutrient rewards derives from the need to acquire necessary substances for survival, reward value is closely related to the state of the animal. Deprivation on a particular substance enhances its subjective value, whereas satiation reduces its value. These states can be general or specific for a substance (e.g., "general" versus "sensory specific" satiety).

Satiation is captured by decreasing marginal utility in gradually flattening (concave) utility functions **(FIGURE 24*A*)**. Higher satiation leads to complete saturation and subsequent repulsion characterized by zero and then negative marginal utility **(FIGURE 24*B*)**, although such satiety does not typically occur with money. In contrast, reward deprivation is captured by the steeper part of the utility function with higher marginal utility.

Rather than directly affecting marginal utility and EU, an alternative account may conceptualize motivational states as likely nonlinear and nonmonotonic utility (EUstate) which adds to EU and results in overall EUnet, similar to other influences described below

$$\text{EUnet} = \text{EU} + \text{EUstate} \quad (11)$$

With deprivation, EUstate is positive and increases EUnet, whereas satiation turns EUstate negative and decreases EUnet. We can distinguish general from sensory specific effects on EUnet by using separate state utilities

$$\text{EUnet} = \text{EU} + \alpha * \text{EUgenstate} + \beta * \text{EUspecstate} \quad (11A)$$

with weighting coefficients α and β. General deprivation and satiety affect all rewards to some extent (EUgenstate), whereas sensory specific satiety affects primarily the particular reward (EUspecstate). The effects of deprivation and satiety on EUnet can be accommodated by the reinforcement framework by substituting EU in *Equations 10A* through *10D* by EUnet.

Satiety on individual rewards reduces behavioral reactions and neuronal responses in monkey orbitofrontal cortex to the smell, taste, and sight of rewards (105) and in ventromedial prefrontal cortex to water (58). The response decrease is specific for the satiating reward, including blackcurrant, cream, vanilline, limonène, or monosodium glutamate liquids (105). Some responses to the nonsatiating rewards remain uninfluenced, suggesting sensory specific rather than general satiety. General satiety over the daily course of the experiment reduced most responses of dopamine neurons to auditory cues for food pellets in mice (496). Opposite to satiation, salt depletion makes salt rewarding. Rats show behavioral approach to NaCl solutions after, but not before, salt depletion by furosemide while reward neurons in the ventral pallidum begin to respond to salt (472, 591). These results provide neuronal correlates for the influence of motivational states on subjective value compatible with *Equation 11*.

4. Context

Rewards occur always in an environmental context, and these contexts exert considerable influence on subjective reward value. Imagine yourself in a gourmet restaurant and hearing a loud "wow." Then imagine watching a tennis match and hearing the same "wow." Obviously the behavioral reaction to the "wow" differs depending on the context, suggesting that information from the context (restaurant versus tennis) affects the interpretation of the explicit event ("wow"). Adding a nonlinear subjective value function EUcxt captures the value gained by rewarded contexts

$$\text{EUnet} = \text{EU} + \text{EUcxt} \quad (12)$$

Animal learning theory conceptualizes the influences of context on behavioral reactions in several forms. In general, Pavlovian-instrumental transfer, instrumental (operant) learning is enhanced in the presence of a previously Pavlovian conditioned stimulus compared with an unconditioned stimulus (145). In renewal, previously extinguished conditioned responding may return depending on the contextual environment (59). In pseudoconditioning, a primary reinforcer endows the context and all its cues with reward value through conditioning. Pavlov noted "a conditioned reflex to the environment" (423) and Konorski mentioned "conditioned to situational cues" (289). Pseudoconditioning elicits approach behavior to unpaired events in rewarded contexts (367, 536, 537), as if reward properties "spill over" from the context to the explicit event. For example, in an experiment on rabbit jaw movement, the value of the unpaired stimulus was close to 0 (analogous to EU = 0), but amounted to 70% of the value of the rewarded stimulus after that stimulus had been conditioned in the same context (EUcxt = 70% of rewarded stimulus EU) (537). In all these forms, otherwise ineffective stimuli occurring in the same context gain motivational value and induce behavioral responses (191, 335), even though they have never been explicitly paired with the primary reinforcer.

Influences of contextual information are well known from everyday experiences. Labeling an odor as cheese rather than body odor, or describing flavors as rich and delicious rather than vegetable water, increases pleasantness ratings and responses in human orbitofrontal cortex (118, 189). Stating the brand name of soft drinks, like Coke and Pepsi, strongly increases preference ratings for the drink indicated and enhances prefrontal reward responses (352). In wine tasting, stated prices influence pleasantness ratings and value responses in orbitofrontal cortex (432). In risky decisions with only partly known outcomes, additional information of outcomes after the decision may reduce or enhance the value of a received outcome (329). Thus contexts add EUcxt to the EU of odors, flavors, soft drinks, and wine and gambles to modify EUnet.

5. Economic cost

Natural rewards do not only provide nutrients and calories, their acquisition usually requires calorie expenditure that reduces the gains provided by them. We need to work for them, approach them, collect them, and consume them. This intuition applies to all rewards and is conceptualized as economic cost. Every good has its cost, and we usually calculate the net benefit before handing over the money. We need to ensure that the cost does not wipe out the benefit. The value of Eve's apple is reduced by the loss of paradise.

Net benefit utility can be calculated generically as a subtraction

$$\text{EUnet} = \text{EU} - \text{EUcost} \quad (13)$$

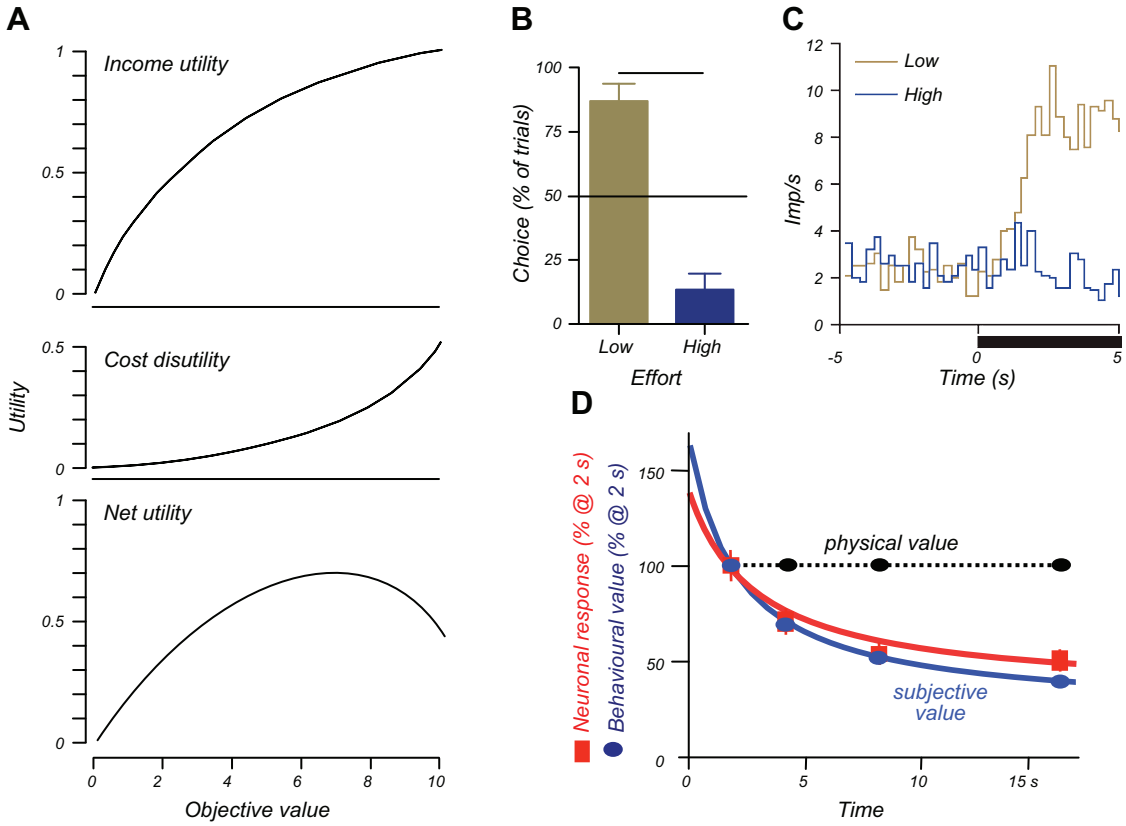

FIGURE 28. Neuronal value coding incorporates reward cost and delay. *A:* construction of net utility from reward cost. Concave income utility (*top*) minus convex cost disutility (*middle*) results in nonmonotonic net utility (*bottom*). *B:* behavioral choice preferences reveal stronger reduction of subjective reward value by high compared with low effort cost (number of lever presses) in rats (income is identical). *C:* stronger reduction of cue response of single rat nucleus accumbens neuron by high (blue) compared with low (gray) effort cost. [*B* and *C* from Day et al. (116). Copyright 2010 John Wiley and Sons.] *D:* temporal discounting in monkey choice behavior (blue) and corresponding responses of dopamine neurons (red) across reward delays of 2–16 s (hyperbolic fittings; n = 33 neurons). [From Kobayashi and Schultz (285).]

Equation 13 is based on physical net benefit, physical income, and physical cost (such as calories)

$$\text{Net benefit} = \text{income} - \text{cost} \qquad (14)$$

and becomes net utility by applying different utility functions u(income) and d(cost)

$$\text{Unet} = \text{u(income)} - \text{d(cost)} \qquad (15)$$

Income utility u(income) is often concave (gradually flattening due to decreasing marginal utility) (**FIGURE 28A**, *top*). Physical effort, as the energy expenditure required to obtaining a reward, is an economic cost, as long as it is associated with the pursuit and acquisition of that reward. As higher efforts become increasingly harder, cost is often assumed to be convex (**FIGURE 28A**, *middle*). With convex cost, the disutility of high effort may outweigh the increase of income utility, resulting in decreasing Unet and thus loss of monotonicity (**FIGURE 28A**, *bottom*). The effort cost in *Equations 13–15* needs to be distinguished from temporal discounting, which may be partly due to another form of cost, opportunity cost, and reduces reward value through a separate mechanism (see *Equations 16-18A*).

A gross simplification may neglect the different curvatures possible with *Equation 15* and apply a common logarithmic utility and disutility function

$$\text{Unet} = \log(\text{income}) - \log(\text{cost}) \qquad (15A)$$

which is equivalent to the benefit-cost ratio

$$\text{Unet} = \log(\text{income/cost}) \qquad (15B)$$

Appropriate behavioral tests would involve separate assessment of income-utility and cost-disutility functions in a common reward value currency, using choices between reward alone [to obtain u (reward)] and reward combined with cost [to obtain d(cost)], similar to composite outcomes involving punishers **(FIGURE 11A)**.

In analogy to temporal discounting (see *Equations 17* and *18* below), alternative effort models used in some neurobiological studies (419, 439) incorporate effort cost into net benefit by exponential discounting

$$\text{Net benefit} = \text{income} * e^{-k*\text{cost}} \qquad (15C)$$

to result in a utility measure

$$\text{Unet} = \text{u(income)} * e^{-k*\text{cost}} \quad (15D)$$

or by hyperbolic discounting

$$\text{Net benefit} = \text{income}/(1 + k * \text{cost}) \quad (15E)$$

$$\text{Unet} = \text{u(income)}/(1 + k * \text{cost}) \quad (15F)$$

where k is discounting factor, reflecting subjective cost sensitivity.

The pursuit of any reward reduces the chance of obtaining another reward. This opportunity cost arises with mutually exclusive rewards and is defined as the value of the highest foregone alternative reward. Thus, in principle, *Equations 13-15D* apply to every reward obtained in the presence of a viable, mutually exclusive alternative. Opportunity cost applies also when rewards are delayed and other beneficial options cannot be pursued, which is conceptualized as temporal discounting (see below).

Movements and effort may not only constitute a cost but also have intrinsic reward value (31, 358, 546, 547). A behavior may be undertaken for the pure pleasure of it and without resulting in any other reward. A kid is having fun building an airplane without getting monetary or social benefits. The intrinsic reward value can be considered as income, the required effort (and missed opportunity for homework) is the cost, and *Equation 15* becomes

$$\text{Unet} = \text{u'(intrinsic income)} - \text{d(cost)} \quad (15G)$$

with u' as utility function distinct from u. Intrinsically rewarding behavior may also lead to extrinsic reward. A mechanic loves to rebuild historic car engines and also sells them well, a typical scenario for people that love their jobs. Here, income utility derives from both intrinsic and extrinsic reward value, and *Equation 15* becomes

$$\text{Unet} = \text{u(extrinsic income)} + \text{u'(intrinsic income)} - \text{d(cost)} \quad (15H)$$

Importantly, the added value from intrinsic rewards may outweigh high effort costs. Even if u(extrinsic income) in *Equation 15H* is below d(cost), Unet remains positive, and the behavior viable, if the utility gained from intrinsic reward [u'(intrinsic income)] is sufficiently high. People that love their jobs may be content with unspectacular pay. Alternative formulations may consider intrinsically rewarding behavior as reward in its own right and apply *Equation 25* for multiple rewards (see below). Taken together, effortful behavior may both enhance and reduce net benefit. As the intrinsic gains and costs of behavior are subjective and not deducible from physical movement measures alone, it is particularly important to assess the involved utilities in choices against a reference utility using quantitative psychophysical methods. Simply assuming that movements represent only an economic cost, and estimating its utility from physical rather than behavioral measures, may be misleading.

Behavioral studies on cost follow primarily *Equation 14*. Experiments involve rats crossing barriers in T mazes (499) or working for intracranial self-stimulation (62) and monkeys performing sequential movements (60) or exchanging tokens for reward (69). Tests on humans sampling different numbers of targets comply with *Equation 15B* (108). Binary choices increase with reward value and decrease with effort cost measured as number of lever presses in monkeys (263) and rats (115, 116, 621) and lever movement against resistance in monkeys (233, 419) **(FIGURE 28B)**. These choice procedures allow comparison of subjective net benefit between the options analogous to Unet, but without explicitly assessing u(income) and d(cost). Behavioral choices are fit better by the physical cost subtraction model of *Equation 14* than by exponential or hyperbolic cost discounting of *Equations 15C* and *15E* (233). Reaction times increase with increasing effort, well fit by exponential or hyperbolic cost discounting of *Equations 15C* and *15E* (419).

Neurons in anterior cingulate cortex show activity increases with income and decreases with effort cost (233, 263), thus following the components of *Equation 14*. In contrast, orbitofrontal and dorsolateral prefrontal cortex neurons code either income or cost but not both (233). Neurophysiological responses and dopamine release evoked by reward-predicting cues in nucleus accumbens decrease with higher fixed ratio effort (115, 116) **(FIGURE 28C)**. Exponential or hyperbolic cost discounting (*Equations 15C and 15E*) affects some dopamine neurons in substantia nigra (419). Thus neuronal responses in reward structures typically reflect the influence of effort cost on reward value.

The dopamine sensitivity to effort is at odds with the failure of finding reductions in voltammetric dopamine reward responses in nucleus accumbens with effort (224, 621). However, the effort in these studies was intercorrelated with temporal discounting, which is well established to reduce reward value and corresponding electrophysiological and voltammetric dopamine responses (116, 158, 285) **(FIGURE 28D)**. Thus it is unclear why not at least temporal discounting reduced the dopamine responses. The effort-insensitive voltammetric dopamine changes were slow (lasting >8 s) and one order of magnitude lower than the typical phasic voltammetric dopamine changes [0.5–15 nM (224, 621) versus 30–70 nM (116)], which raises additional, methodological issues. The slower responses resemble dopamine changes of similar durations and magnitudes that have no correlate in dopamine impulse activity (237). Thus the slower, lower, effort insensitive dopamine changes likely do not reflect subjective value (224) but unlikley bear on the

role of phasic dopamine signals in economic value coding. Thus the slower, lower, effort insensitive dopamine changes may not reflect subjective value (224) which, however, does not bear on the phasic dopamine coding of all subjective value components tested so far, including reward amount (598), reward type (301), risk (156, 301, 560, 570), delay (116, 158, 285), and effort cost (116) all the way to formal economic utility (560).

6. Temporal discounting

Typical primary nutrient rewards, like fruits or meat, mature and decay over time. Once consumable, they risk destruction from many causes including competition by other reward seekers. Rewards often need to be consumed at particular times due of specific energy demands, and later rewards are less tangible in general. Thus specific rewards in specific situations should be harvested at specific moments. This is why we cannot wait for the pay slip, use refrigerators, drink wine at its best age, and mate only after maturation. These temporal constraints favor temporal sensitivity in the evolution of the brain's reward system and lead to personal, potentially beneficial traits of impatience, impulsivity, and risk taking. The characteristics extend to all rewards and explain the variation of subjective reward value over time. Although temporal discounting likely originates in the perishable nature of goods, it occurs even when the reward remains physically unchanged and overall reward rate is held constant, thus dissociating subjective from objective reward value.

Temporal discounting studies focus mostly on monotonic, forward decreases of value (4, 462, 473). However, value may evolve nonmonotonically in time as birds store food (443), often increasing initially and then decreasing, although the inverse is also possible. The change of reward value over time occurs between a reward-predicting stimulus and reward delivery when no operant action is required (Pavlovian conditioning) or between an action and the resulting reward. In animal learning theory, increasing temporal delays decrease the proximity (contiguity) between stimulus or action and reinforcer. Delays position the reward away from the stimulus or action and more into the background, thus reducing the subjectively perceived reward contingency (dependency of reward on stimulus or action) (175, 220). Thus both subjective devaluation and subjective contingency reduction reduce the power of reinforcers for learning.

Temporal discounting constitutes an opportunity cost when waiting prevents individuals from other activity leading to reward or from using the reward for beneficial investments. Thus temporal discounting can be stated generically as an economic cost, in analogy to *Equation 13*

$$\mathrm{EUnet} = \mathrm{EU} - \mathrm{EUtemp} \qquad (16)$$

Obtaining net benefit Unet requires two steps, assessment of u(m) from objective reward magnitudes and then its temporal discounting (296). Temporal discounting can be implemented by exponential functions, resulting in constant discount rate

$$\mathrm{Unet} = \mathrm{u}(m) * e^{-k*\mathrm{D}} \qquad (17)$$

where k is discount factor. D is subjective delay, as assessed from maximal responses at the subjectively perceived delay (peak interval procedure, Ref. 469). Alternatively, hyperbolic functions show initially higher and then gradually decreasing discounting (5, 218)

$$\mathrm{Unet} = \mathrm{u}(m)/(1 + k * \mathrm{D}) \qquad (18)$$

Hyperbolic discounting is particularly prominent against immediate rewards. When all rewards have longer delays, exponential discounting may describe the process better. The generalized hyperbola combines the two models by adding a free parameter a (325)

$$\mathrm{Unet} = \mathrm{u}(m)/(1 + k * \mathrm{D})^{a/k} \qquad (18A)$$

Unet can be assessed psychophysically with intertemporal choices between a variable early and a constant delayed reward (adjusting-amount procedure). Unet of the late reward is inferred from the utility of the early reward that produces choice indifference. Unet in monkeys decreases monotonically across delays of 2, 4, 8, and 16 s by ~25, 50, and 75%, respectively (**FIGURE 28*D***, blue) (285), with slightly better fits by hyperbolic than exponential discount functions. Temporal discounting decreases from rodents to monkeys to humans.

Some theories of temporal discounting distinguish between a prefrontal system controlling immediate, impulsive consumption and a separate valuation system (352, 538), whereas more straightforward accounts assume that a single reward value system directly discounts value according to *Equations 16-18A*, although the truth might lie in between. Some reward value coding neurons in all reward systems show decreased responses with increasing delays. Responses of monkey dopamine neurons to reward-predicting stimuli decrease monotonically across reward delays of 2–16 s (**FIGURE 28*D***, red), despite constant physical reward magnitude, thus matching closely the behavioral discounting (compare blue and red) (158, 285). Corresponding to human behavior (277), lower reward magnitudes are associated with steeper neuronal discounting (285). The same dopamine neurons code reward magnitude. Temporal discounting may reflect reduced value at the time of the predictive stimulus (input stage) or during the decision process (output stage). The reduced dopamine response occurs in imperative tasks without choices, suggesting value alterations in the input stage. The reduced neuronal response leads to reduced dopamine release in nucleus accumbens (116). Inversely, dopamine prediction error responses to reward delivery increase with longer delays. Both responses are fit better by hyperbolic than exponential func-

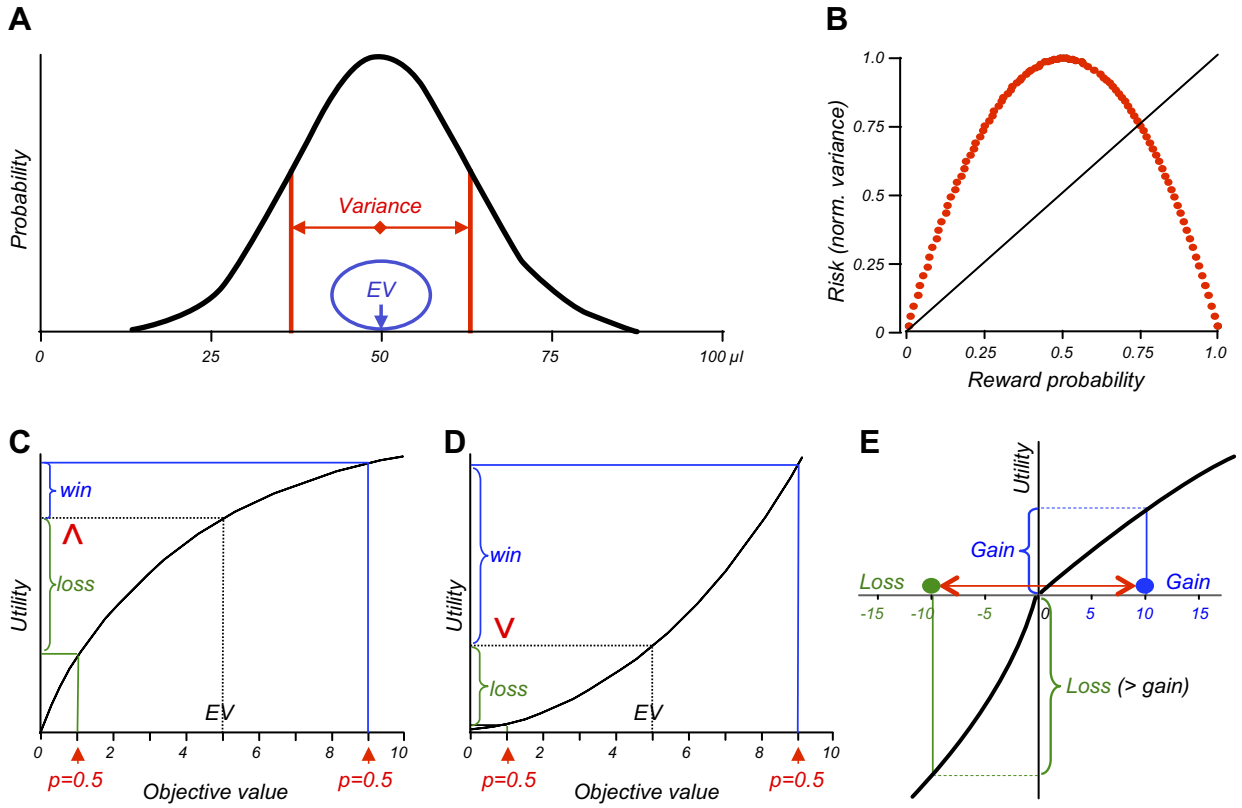

FIGURE 29. Risk and utility functions. *A:* two principal measures in probability distributions (density function). Expected value (EV, first raw moment) denotes value. Variance (second central moment) denotes spread of values and is a good measure for symmetric risk. Red arrows show ± 1 units of standard deviation (SD; square root of variance). Not included are other important risk measures, including informational entropy and higher statistical moments such as skewness and kurtosis. *B:* variance risk (normalized) as a nonmonotonic function of probability. For contrast, dotted line shows monotonic increase of value with probability. *C:* concave utility function associated with risk avoidance. The risky gamble (red, 1 vs. 9, each at $P = 0.5$) induces stronger utility loss when losing the gamble (green) than the gain when winning the gamble (blue) relative to the utility of the expected value of the certain outcome (EV = 5). *D:* convex utility function associated with risk seeking. Gain from gamble win is stronger than loss from gamble losing. *E:* explaining subjective risk notions by gain-loss functions. Due to the steeper loss slope ("loss aversion"), the loss from the low outcome of the binary gamble looms larger than the gain from the high outcome. Hence, risk is often associated with the notion of loss. [Value function from Kahneman and Tversky (258), copyright Econometric Society.]

tions. The almost perfect overlap between behavioral and neuronal discounting **(FIGURE 28*D*)** suggests that temporal delays affect dopamine responses via changes in subjective reward value. Dopamine neurons process delayed rewards as having less value.

Many reward value coding neurons in other reward structures show temporal discounting, including orbitofrontal cortex (478), prefrontal cortex (272, 475), anterior cingulate (233), premotor cortex (475), parietal cortex (477), and dorsal and ventral striatum (79, 115). Reversal of cue-delay associations leads to reversed neuronal responses, suggesting an influence of delay rather than visual properties (475). Often the same neurons code also reward magnitude (476), suggesting common subjective value coding across different rewards. Taken together, neuronal population in all major reward structures code subjective reward value during temporal discounting.

7. Risk

Rewards are, as all environmental events, inherently uncertain. The uncertainty can be formally approached via the description of rewards as probability distributions of values. In contrast to the first statistical moment of probability distributions that defines value (EV, *Equation 8*), the higher moments reflect risk, including variance, skewness, and kurtosis **(FIGURE 29*A*)**. Risk refers to the degree of uncertainty in known probability distributions, whereas ambiguity denotes uncertainty when probability distributions are incompletely known. Risk, and also ambiguity, has at least three functions in reward processing. First, individuals should perceive risk appropriately, irrespective of making a decision at a given moment. Second, as the terms of risk avoidance and risk seeking indicate, risk affects the subjective value of rewards. These two functions, and their processing by reward neurons, will be described in this section.

Third, risk informs about the spread of reward probability distributions which neurons may take into account when processing reward value within an existing distribution. This function will be described subsequently as adaptive processing.

Popular risk measures are variance

$$\text{var} = \sum_i [p_i(m_i) * (m_i - \text{EV})^2]; \text{ over all } i \quad (19)$$

where P is probability and m is magnitude. Standard deviation (SD), the square root of variance, is also a good and frequently used risk measure. EV and SD fully define Gaussian and equiprobable binary probability distributions. However, the coefficient of variation, CV = SD/EV, is often a better measure for risk in economic choices (633). Other risk measures are Shannon informational entropy (analogous to thermodynamic entropy) that seems appropriate for neuronal information processing systems (477).

Although probabilistic rewards are intrinsically risky, probability is not a monotonic measure for risk but for value (*Equation 8*). Whereas reward value increases monotonically with probability, variance as a measure for risk follows probability as an inverted U function **(FIGURE 29*B*)**. It peaks at $P = 0.5$ where the chance to gain or miss a reward is equal and maximal. Variance risk is lower at all other probabilities with more certain gains and misses.

Risk is perceived subjectively through genuine risk avoiding/seeking tendencies ("I hate/love the risk"), risk distortions ("I have no idea/am confident about the outcome"), the value at which loss/win occurs ("no gambling at high values/peanuts"), the domain, situation, and familiarity of the risky event, and hormones (86, 87, 630, 632). Some of these factors may play a role when defining subjective risk in analogy to *Equation 19* as variance of utility

$$\text{varU} = \sum_i \{\pi[p_i(m_i)] * [\text{u}(m_i) - \text{EU}]^2\}; \text{ over all } i \quad (20)$$

A fuller account would include more of the mentioned subjective factors.

It is important for the understanding of risk attitude to distinguish between objective and subjective value. The famous example is the hungry bird with challenged energy balance (87). The bird requires 100 calories to survive the night and has the choice between a certain option of 90 calories and an equiprobable gamble of 0 and 110 calories ($P = 0.5$ each). The bird would hopefully choose the gamble, as this provides it at least with a 50% chance of survival. However, from the perspective of objective value, the usually risk-avoiding bird seems to be surprisingly risk seeking, as it prefers a risky option with an EV of 55 calories over a certain 90 calories. However, the bird's behavior follows first-order stochastic dominance when we consider survival values (0 vs. 0/1 survival), which tests for meaningful and rational choices (341).

Risk avoidance and risk seeking suggest that risk affects economic choices, which can be visualized via the curvature of the utility function (*Equation 9*). With concave utility **(FIGURE 29*C*)**, the initially steeper slope indicates higher marginal utility in lower ranges. Losses move utility into the lower, steeper range and thus appear subjectively more important than gains which move utility into the upper, flatter range, resulting in risk avoidance. In contrast, with a convex utility function **(FIGURE 29*D*)**, the steeper slope in higher ranges makes gains appear subjectively more important than losses, thus encouraging risk seeking. In some cases, the curvature of utility functions can change, often from risk seeking with low values to risk avoidance with high values. Risk seeking at low values may suggest that the attraction of gambling outweighs potential losses ("peanuts effect") (152, 436, 630).

The subjective value of risk combines with riskless utility to result in the utility of risky choices, as expressed generically

$$\text{EUnet} = \text{EUrl} - \text{EUrisk} \quad (21)$$

with EUrl as riskless utility, and EUrisk as disutility due to risk. This approach recognizes the difference between riskless and risky utility functions (631). Positive EUrisk reduces EUnet and characterizes risk avoidance, whereas negative EUrisk enhances utility and characterizes risk seeking. This approach follows in kind the construction of utility from objective measures of risky outcomes (EV and variance) by the mean-variance approach in financial economics based on Taylor series expansion (238, 315)

$$\text{EU} = \text{EV} - b * \text{variance} \quad (21A)$$

with b as subjective risk weighting coefficient. *Equation 21A* applies, strictly spoken, only to quadratic utility functions.

In addition to subjective risk perceptions, the subjective effect of risk is determined by the curvature of utility functions that are typically concave **(FIGURE 29*C*)** and asymmetric for gains and losses (steeper gain functions, or steeper loss functions inducing "loss aversion") (258). Subjective pessimistic/optimistic probability distortions are further subjective influences ("today is my bad/lucky day"). These subjective factors transform symmetric variance risk into the common asymmetric notion of risk as the danger to lose (higher loss than gain utility) **(FIGURE 29*E*)**.

The most simple and controlled risky outcome is provided by a binary, equiprobable gamble ($P = 0.5$ each outcome) in which risk can be varied without changing the EV (mean-preserving spread) and which has negligible, constant probability distortion and is not skewed (497) **(FIGURE 30*A*)**. Risk attitude can be estimated by eliciting the certainty

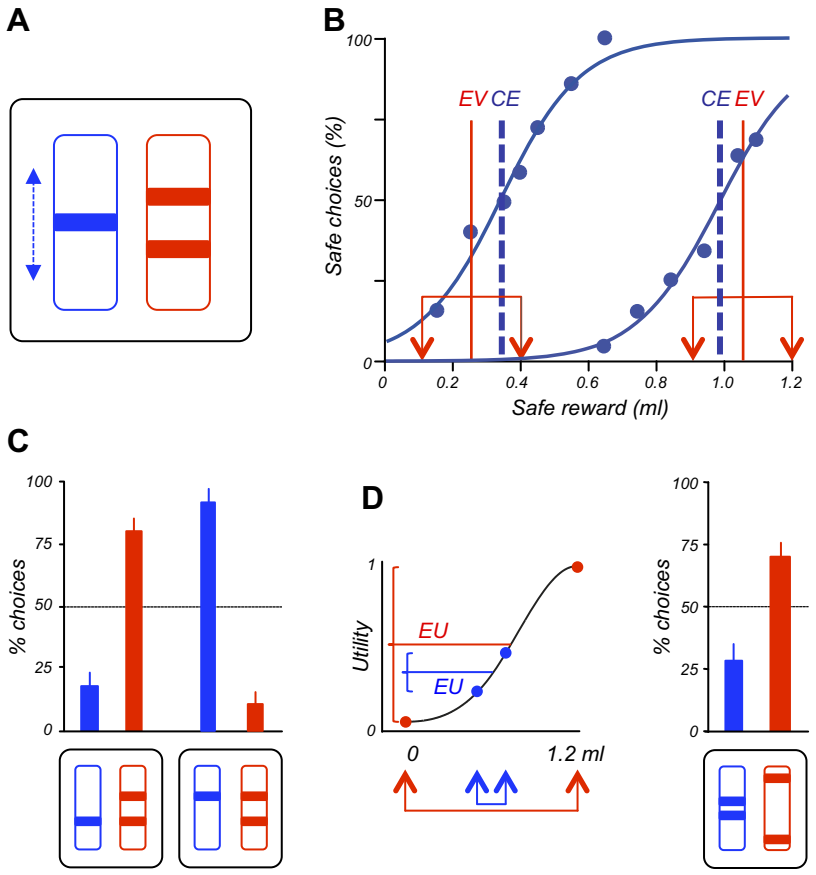

FIGURE 30. Behavioral risk measures in monkeys. *A:* stimuli indicating an adjustable certain (riskless, safe) outcome (blue) and a minimal risky binary gamble (red). Heights of horizontal bars indicate reward magnitude (higher is more). Typically, each gamble outcome occurs with probability $P = 0.5$. *B:* psychophysical assessment of subjective value of binary risky gambles by eliciting the certainty equivalent (CE). The CE is the value of the adjustable certain (riskless, safe) outcome at which choice indifference against the risky gamble is obtained (oculomotor choices in monkeys). A CE exceeding expected value (EV) indicates risk seeking (gamble at *left*), CE < EV indicates risk avoidance (*right*). Red arrows indicate the two outcomes of each gamble. *C:* choices for better options satisfy first-order stochastic dominance in monkey, indicating meaningful choice behavior. In choices against an equiprobable gamble ($P = 0.5$ each outcome), monkeys avoid the low certain reward (set at low gamble outcome, *left*) and prefer the high certain reward (set at high gamble outcome, *right*). Averaged data from binary choices involving four gambles: 0.1–0.4 ml, 0.5–0.8 ml, 0.9–1.2 ml, 0.1–1.2 ml. *D:* choices for riskier options with mean preserving spread satisfy second-order stochastic dominance for risk seeking in monkey, indicating meaningful incorporation of risk into choices. When presented with gambles in the risk-seeking domain of the utility function (left; expected utility, EU, higher for riskier gamble, red), monkeys prefer the riskier over the less risky gamble. [*B–D* from Stauffer et al. (560).]

equivalent (CE) in behavioral choices between an adjustable certain (riskless) outcome and a risky gamble. The CE is defined as the value of the certain option at choice indifference against the risky option. It is lower than EV in risk avoiders and higher in risk seekers. The risk premium reflects the value reduced or added by risk (CE < EV or CE > EV, respectively). The risk premium is usually defined as EV − CE (>0 for risk avoidance, <0 for risk seeking, 0 for risk neutrality), or sometimes as EV/CE (>1 for risk avoidance, <1 for risk seeking, 1 for risk neutrality) (558). Rhesus monkeys are often risk seeking with standard small liquid volumes (CE > EV) and risk avoiding with volumes above 0.5–0.8 ml (CE < EV) **(FIGURE 30*B*)** (355, 560, 644). Their utility function is initially convex, then linear and ultimately concave **(FIGURES 24*D* AND 27*A*)**, thus showing an inflection as conceptualized and found in human utility functions (152, 339, 436, 630).

Formal tests of stochastic dominance (341) confirm that monkeys understand the risky stimuli (560). First-order stochastic dominance helps to define meaningful choices without requiring assessment of a utility function. However, higher EV does not necessarily satisfy first-order stochastic dominance, due to nonlinear utility, nonlinear probability weighting, and risk attitude. In statewise dominance, a case of first-order stochastic dominance, a gamble dominates another gamble if all its outcomes are equal except at least one outcome that is better. Monkeys' behavior satisfies this criterion in choices between a certain reward and an equiprobable, binary gamble whose low or high outcome equals the certain reward. They avoid the low certain reward (**FIGURE 30*C***, *left*) and prefer the high certain reward to the gamble (*right*). Second-order stochastic dominance tests whether risk is incorporated into subjective reward value in a consistent fashion. Monkeys' choices satisfy also this test. With mean preserving spreads, they prefer more risky over less risky gambles in the lower, risk-seeking range of reward volumes **(FIGURE 30*D*)** and show stronger risk preference against certain outcomes (391). Also, monkeys prefer risky over ambiguous options (207). Thus monkeys make meaningful choices under risk consistent with expected utility theory.

The orbitofrontal cortex plays a key role in risky choices (317). Human patients and animals with lesions in orbitofrontal cortex or nucleus accumbens show altered risk and ambiguity sensitivity distinct from value (35, 88, 174, 240, 268, 364, 370, 445). Correspondingly, specific orbitofrontal neurons in monkeys show responses to stimuli predicting binary, equiprobable gambles **(FIGURE 31*A*)** (391). These risk responses occur irrespective of visual stimulus properties and only very rarely reflect reward value, which is coded in separate orbitofrontal neurons. The absence of value coding argues also against the coding of salience, which is associated with both risk and value. Some monkey orbitofrontal neurons are activated by unsigned (absolute)

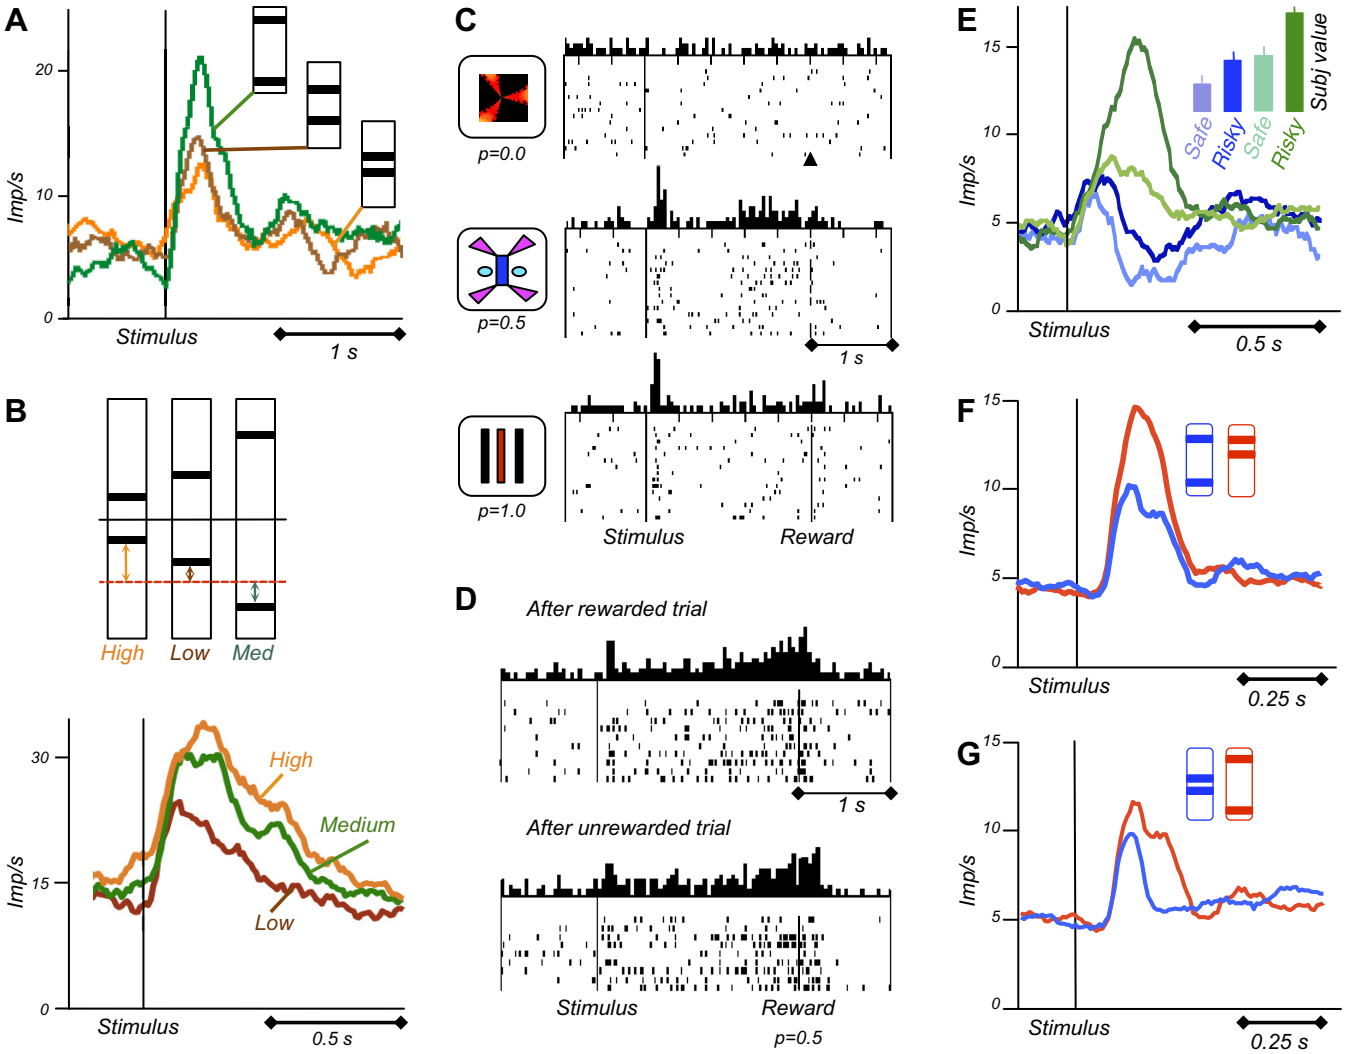

FIGURE 31. Neuronal risk processing in monkeys. *A:* coding of risk in single neuron of orbitofrontal cortex. Height of bars indicates liquid reward volume, two bars within a rectangle indicate an equiprobable gamble (P = 0.5 each). The three gambles have same mean but different variance (9, 36, and 144 ml × 10^{-4}) (mean-preserving spread). This neuron, as most other orbitofrontal risk neurons, failed to code reward value (not shown). [From O'Neill and Schultz (391), with permission from Elsevier.] *B:* coding of risk prediction error in orbitofrontal cortex. *Top*: risk prediction error (colored double arrows), defined as difference between current risk (vertical distance between bars in each gamble indicates standard deviation) and predicted risk (common dotted red line, mean of standard deviations of the three gambles). Colored double vertical arrows indicate unsigned (absolute) prediction errors in variance risk. *Bottom*: averaged population responses from 15 orbitofrontal neurons to unsigned risk error. Such signals may serve for updating risk information. [From O'Neill and Schultz (392).] *C:* risk coding in single dopamine neuron during the late stimulus-reward interval. The activation is maximal with reward probability of P = 0.5, thus following the inverted U function of variance risk shown in **FIGURE 29*B***. Trials are off line sorted according to reward probability. [From Fiorillo et al. (161).] *D:* independence of risk activation in single dopamine neuron from reward outcome in preceding trial. Activation is not stronger after positive prediction errors (*top*) than after negative prediction errors (*bottom*). Thus prediction error responses do not backpropagate in small steps from reward to stimulus. Both rewarded and unrewarded current trials are shown in each graph. [From Fiorillo et al. (162).] *E:* influence of risk on subjective value coding in dopamine neurons. The population response is stronger with subjectively higher valued certain (safe) juice rewards (green: blackcurrant; blue: orange; both 0.45 ml), demonstrating value coding. This value response is enhanced with risky juice volumes (equiprobable gamble of 0.3 and 0.6 ml, same mean of 0.45 ml), corresponding to the animal's risk seeking attitude (higher subjective value for risky compared with certain rewards, *inset*). [From Lak et al. (301).] *F:* dopamine responses satisfy first-order stochastic dominance, demonstrating meaningful processing of stimuli and reward value under risk (averages from 52 neurons). In the two gambles (blue, red), the higher outcomes are equal, but the lower red outcome is higher than the lower blue outcome, defining gamble dominance. *G:* dopamine responses satisfy second-order stochastic dominance, demonstrating meaningful incorporation of risk into neuronal utility signal (averages from 52 neurons). The red gamble has greater mean-preserving spread than the blue gamble, defining dominance with risk seeking. [*F* and *G* from Stauffer et al. (560).]

risk prediction errors, defined as unsigned difference between current and predicted risk, which may serve for updating risk information (FIGURE 31B) (392). In a categorical discrimination task, responses in orbitofrontal neurons reflect the riskiness of olfactory stimuli but in addition differentiate between correct and erroneous choices in correlation with decision confidence (264). The orbitofrontal risk signal is distinct from movement-related activity (153), some of which correlates with particular, asymmetric forms of salience (393). In human prefrontal cortex, BOLD signals show direct risk coding, distinct from value (599), which reflects risk perception irrespective of choice. Outside of orbitofrontal cortex, supplementary eye field neurons differentiate categorically between certain and risky trials and code certain and risky reward value differentially (551), and septum neurons show slow risk responses closely resembling the risk ramp of dopamine neurons (373).

Dopamine neurons code reward risk during the stimulus-reward interval after the value prediction error response (FIGURE 31C) (161). The activation ramps up to the reward and varies with probability in an inverted U function, analogous to risk measures such as variance, standard deviation, and entropy. It increases with variance and standard deviation, even when entropy is kept constant. Thus the signal reflects risk rather than value (FIGURE 29B). An analogous signal is also seen in the human ventral striatum, which is distinct from value and most likely reflects synaptic activity induced by the electrophysiologically measured dopamine risk signal (437). Although its latency is too long for immediate decision processes, the dopamine risk signal might affect the subsequent prediction error signal at the time of the reward. In coding risk, the signal varies with surprise salience and thus may affect the learning constant of attentional (associability) learning theories (425, 336). Also, the slower risk signal might contribute to the risk sensitivity of the faster, phasic dopamine signal (see below) (156, 301, 560, 570).

Straightforward implementations of TD models may produce similar ramps by backpropagation of prediction error responses from reward to the preceding conditioned stimulus in small steps via imaginary stimuli (374, 524), thus resembling the dopamine risk response (388). As the backpropagating activation would be small and dispersed, it would appear as ramp only when averaging across multiple trials (183, 388). However, the dopamine risk signal occurs in single trials without averaging and does not backpropagate via imaginary stimuli, as suggested by its absence after prediction errors (FIGURE 31D) (161, 162), but jump in single steps from reward back to the preceding actual stimulus (FIGURE 14A) (117, 410, 598). The ramp is not a necessary feature of TD models but occurs only in specific implementations (374, 388, 524). Biologically more plausible TD implementations and spectral timing models use stimulus eligibility traces, as originally suggested (FIGURE 14B) (574), and model well the single step backward transition of dopamine prediction error responses from reward to the next preceding conditioned stimulus without error backpropagation and thus without a ramp during the stimulus-reward interval (FIGURE 14, C AND D) (71, 410, 573). In particular, models using a biologically consistent striatal and midbrain circuit replicate well the dopamine risk ramp (581). Thus the dopamine ramp represents a genuine risk response and not the necessary byproduct of TD models.

In addition to the late and slow dopamine risk signal, risk affects the phasic dopamine value response. The subjective reward value signal of dopamine neurons is enhanced when monkeys prefer risky over certain outcomes of low or intermediate reward magnitudes (FIGURE 31E) (156, 301), suggesting incorporation of risk into the final construction of utility in possible compliance with *Equation 21A*. Correspondingly, dopamine concentration changes following risky cues are reduced in risk avoiding rats and enhanced in risk seekers (570). In formal tests informed by economic theory (341, 497), dopamine responses follow first- and second-order stochastic dominance (FIGURE 31, F AND G), suggesting meaningful coding of economic value and risk and incorporation of risk into neuronal substrates of subjective value. Thus three types of experiment demonstrate that dopamine neurons incorporate risk appropriately into neuronal substrates of subjective value and formal utility, namely, value responses modified by risk in correspondence with risk attitude (FIGURE 31E), second-order stochastic dominance between different risky outcomes (FIGURE 31G), and processing of utility assessed via CEs across risk seeking and risk avoiding domains (FIGURE 27B) (560).

Risk influences also subjective value coding in orbitofrontal cortex (444, 482) and modifies saccadic activity in posterior cingulate cortex (355). In human prefrontal cortex, risk affects value responses in close correspondence to individual risk attitudes in analogy to *Equation 21A* (596). Direct risk coding for risk perception and incorporation of risk into subjective value constitute two different processes that allow multiple uses of risk information for behavior.

Taken together, the distinct neuronal coding of value and risk suggest that Pavlovian reward predictions concern probability distributions defined by value and risk. In contrast to reward magnitudes that impact directly on sensory receptors, the coding of EV, probability, and risk of reward is not explained by peripheral sensory stimulation but requires central neuronal mechanisms including memory. Irrespective of these implementation details, the separation of reward signals according to the statistical moments of probability distributions, and the possible correspondence to Taylor series expansion, provides a biological basis for the mathematical treatment of rewards as probability distributions, demonstrates the biological plausibility and imple-

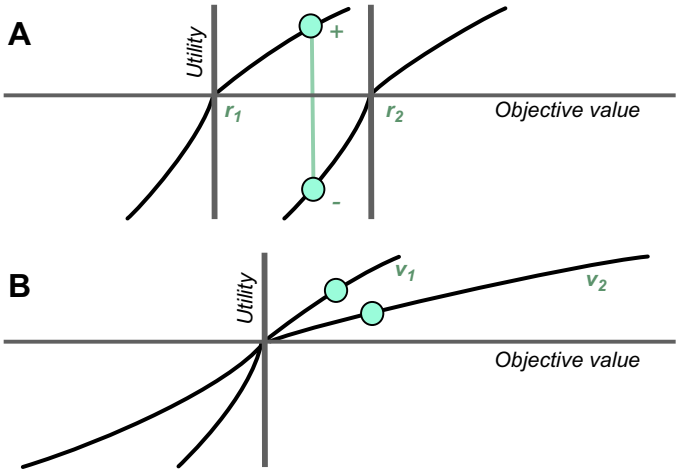

FIGURE 32. Scheme of adaptive reward processing. *A:* adaptation to expected value (r_1, r_2): shift of reference point changes utility gain to loss for identical objective values. *B:* adaptation to variance (v_1, v_2): slope adaptation to variance results in larger utility for lower objective value. [Value function from Kahneman and Tversky (258), copyright Econometric Society.]

mentation of these mathematical concepts, and incorporates them into the neuronal basis of learning theory.

8. Adaptive processing

Whereas the number of neurons and their maximal firing rate limits the processing capacity of the brain, the number of possible rewards is huge. Dedicating equal processing capacity to all possible rewards would lead to low slopes of reward-response functions and thus poor reward discrimination. However, reward availability varies considerably between situations. An efficient discrimination mechanism would restrict neuronal processing to the rewards that are currently available in a given environment, similar to sensory adaptation to probability distributions of ambient visual intensities (148, 235, 307).

For optimal response slopes and thus best use of the limited neuronal coding range, reward processing may adapt to all statistical moments of reward distributions, including EV and variance **(FIGURE 29*A*)**. When schematically separating these two moments, changes in EV lead to processing shifts with maintained response slopes **(FIGURE 32*A*)**, whereas variance affects response slopes, which become steeper with narrower distributions and flatter with wider distributions **(FIGURE 32*B*)**. These adaptations lead to optimal reward discrimination with steepest possible response slopes while maintaining as wide reward coverage as possible.

The consequences of adaptive processing are changes in net utility, which may be expressed generically by adding a term (EUadapt) that summarily covers adaption to all statistical moments of the current probability distribution of objective values

$$\mathrm{EUnet} = \mathrm{EU} - \mathrm{EUadapt} \qquad (22)$$

This approach includes reference-dependent valuation in prospect theory derived from *Equation 10*

$$\mathrm{EU} = \sum_i \{u(m_i - r) * \pi[p_i(m_i)]\};\ \text{over all } i \qquad (22A)$$

with r as reference value (258). The term r is replaced by EVr if reference r derives from a probability distribution rather than being a single value

$$\mathrm{EU} = \sum_i \{u(m_i - \mathrm{EV}r) * \pi[p_i(m_i)]\};\ \text{over all } i \qquad (22B)$$

Equation 22B describes adaptation to the first moment of the probability distribution of objective values. The adaptation to EV can lead to vastly different utilities for identical objective values **(FIGURE 32*A*)**.

A milder approach to reference-dependent valuation combines nonadapted and adapted utility (290). This approach would refine the generic *Equation 22* to

$$\mathrm{EUnet} = \alpha\mathrm{EU} + \beta(\mathrm{EU} - \mathrm{EUadapt});\ \alpha + \beta = 1 \qquad (22C)$$

α and β are additional weighting coefficients. In the terminology of Köszegi and Rabin (290), EU represents consumption utility, and (EU-EUadapt) is reference dependent gain-loss utility. Thus EUnet consists of weighted absolute and relative utilities. Considering nonadapted value recognizes the fact that we know cognitively the absolute reward value, even though we value it relative to references or discount it over time. We know that \$100 is still the same \$100 irrespective of having received \$50 or \$500 the last time around, even though we may feel more elated receiving them as a positive than negative surprise.

Adaptive processing may not be limited to a single reference value and should be extended to full distributions. Inclusion of other statistical moments such as variance adds slope changes. We extend *Equations 10* and *22B* by introducing ω for slope adaptation to variance (or standard deviation)

$$\mathrm{EU} = \sum_i \{u[\varpi * (m_i - \mathrm{EV}r)] * \pi[p_i(m_i)]\};\ \text{over all } i \qquad (22D)$$

A convenient term for ω is 1/standard deviation (384, 438). The adaptation to variance can lead to larger utilities for identical or even lower objective values **(FIGURE 32*B*)**.

Adaptations to reward probability distributions underlie several interesting behavioral phenomena. The negative contrast effect derives from a downshift of reward and reduces behavioral reactions and preferences compared with the same low reward occurring without preceding higher values (51, 104, 593), even when the lower outcome adds value (513). A positive but less prominent contrast effect exists also. The opponent process theory of motivation ac-

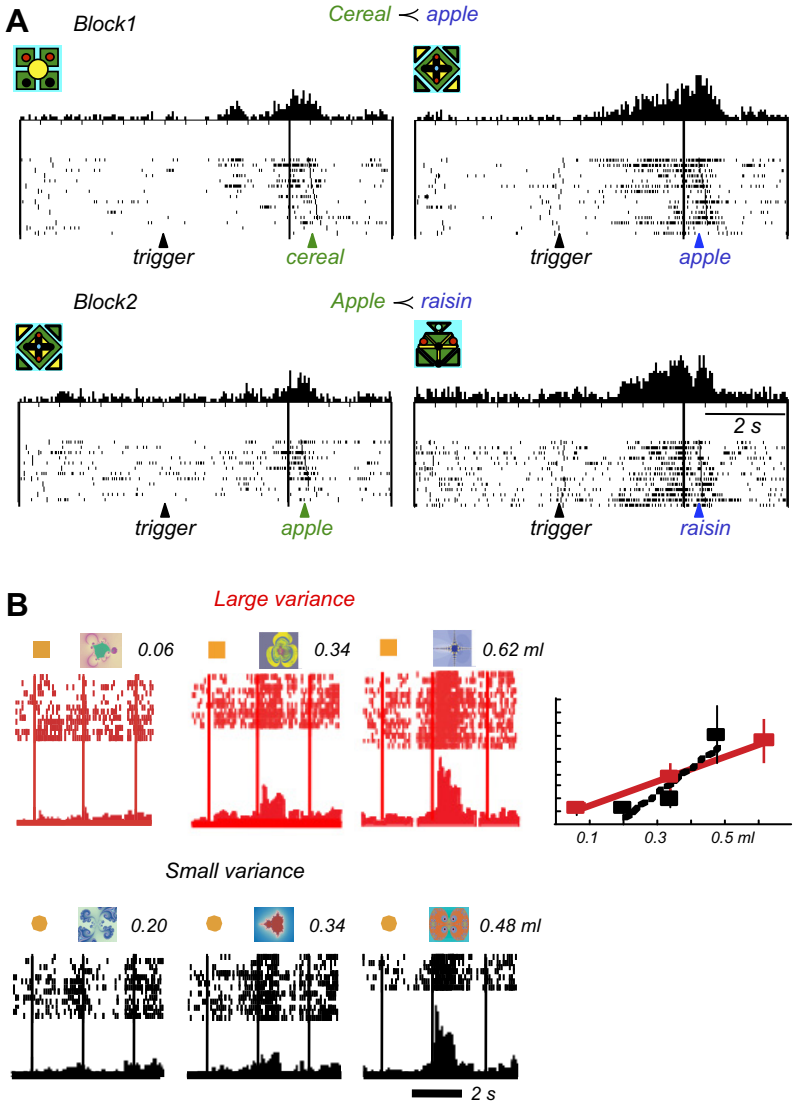

FIGURE 33. Adaptive neuronal reward processing in monkey orbitofrontal cortex. *A:* response adaptation to approximate expected subjective value in single neuron. Trial block 1 offers pieces of cereal or apple, separate block 2 offers same apple (indicated by same stimulus) or raisin. Behavioral choices ranked cereal < apple < raisin. Visual instructions predict type of reward, trigger stimuli elicit arm movement leading to reward. [From Tremblay and Schultz (601).] *B:* response adaptation to variance of reward amount (ml) in single neuron. *Inset* shows change of reward-response regression slope in same neuron. [From Kobayashi et al. (284).]

counts for observations indicating that cessation of reward is aversive, whereas end of punishment is rewarding (552). This effect may well derive from short-term adaptation to the initial reward or punishment, respectively. Adaptations to distributions may also explain the dichotomy in humans between "experienced utility" reflecting utilitarian, hedonic value (39) and "decision utility" measured in overt choices, although overweighting of recent and maximal value is also important (259). This effect is also seen in monkeys (52). The distinction may explain irrational, suboptimal, dominated choices. Monkeys favor [one food morsel plus a 50% chance of a second morsel] over [two food morsels with 50% chance of losing one], although EVs are both 1.5 morsels, although endowment effect and loss aversion may also play a role (91).

Reward responses in dopamine neurons, striatum, amygdala, parietal cortex and orbital, dorsolateral, and cingulate prefrontal cortex adapt to reward magnitude and reward probability distributions as suggested by *Equation 22* (137, 628). More formally, the adaptations may occur to changes in EV (**FIGURE 33*A***) (42, 106, 232, 601), variance (**FIGURE 33*B***) (284, 420, 598), or both combined (80, 403). In subtracting reward value from the mean (prediction error) and dividing it by standard deviation, dopamine neurons code a z-score of reward value (598). Divisive normalization from sensory physiology describes well the adaptations to changes in individual values of choice options in reward neurons of parietal cortex (332). The ventral striatum is importantly involved, as lesions here reduce reward contrast in rats (326). Taken together, the adaptations would be driven by neuronal EV and risk signals and result in a match between the probability distribution of neuronal responses and the probability distribution of current reward values. The result would be dynamically varying, optimal reward response slopes and thus efficient reward processing for choices. The loss of the actual values would be immaterial in choices comparing the options relative to each other. Thus, in adapting to the two key moments of reward probability distributions, reward neurons make ef-

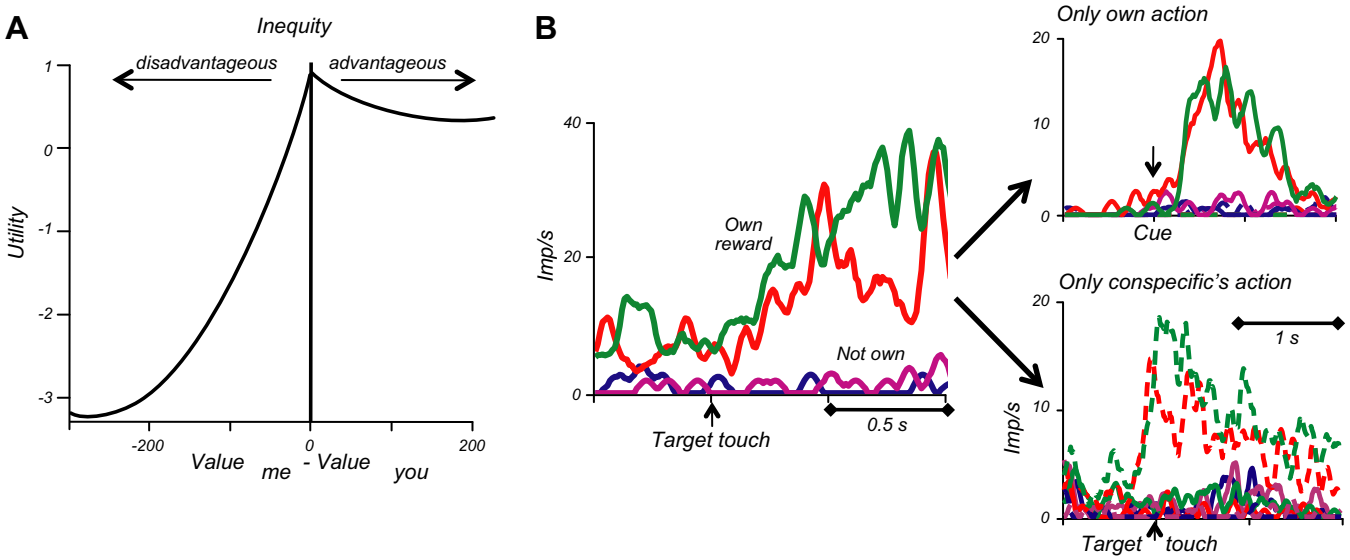

FIGURE 34. Social reward processing. *A:* social reward inequity aversion. Difference between own and other's reward reduces my utility. Usually, disadvantageous inequity (getting less than others, negative difference, *left*) has stronger and more consistent effects than advantageous inequity (getting more than others, *right*). [From Loewenstein et al. (324).] *B:* action-dependent coding of social reward in single striatal neurons. In the imperative reward giving task (modified dictator game), two monkeys sit opposite each other across a touch-sensitive computer monitor and give reward to itself and the conspecific. *Left*: neuronal activation when receiving own reward, either only to itself (red) or together with conspecific (green), but no activation with reward only to conspecific (violet) or to nobody (blue). *Right*: activation with own reward occurs only with own action (*top*, continuous lines) or only with conspecific's action (*bottom*, dotted lines, different neurons between *top* and *bottom*). [From Báez-Mendoza et al. (25).]

ficient use of processing resources for optimal reward discrimination and choice.

The EU shift between environments and the slope adaptation may result in lower utility of higher absolute reward values **(FIGURE 32*B*)**. Thus adaptation may lead to violation of rank order, menu invariance, independence from irrelevant alternatives, and transitivity, which are crucial for meaningful economic choices. However, at least two processes may serve to maintain transitivity in the presence of adaptive valuation. First, the mentioned predictive EU and risk signals in dopamine neurons (598) and orbitofrontal cortex (391) convey information about the two key moments of the reward probability distribution of each environment. These signals may combine with the adapted value signal to generate an accurate, absolute, nonadapted value signal and thus maintain transitivity at the neuronal level. Second, adaptations require time and may only concern subpopulations of reward neurons. Indeed, only a fraction of orbitofrontal reward neurons show adaptation, whereas the remainder codes reward magnitude irrespective of other rewards (403, 406, 284). Although longer test periods might have increased the number of adapting neurons, some orbitofrontal reward neurons seem to code nonadapted, absolute value necessary for maintaining transitivity. Adaptation and absolute value coding by different neuronal populations would combine efficacy with transitivity.

9. Social rewards

Observation of social partners and comparison of rewards between them is crucial for competition and cooperation that improve performance and give individuals access to otherwise unobtainable resources and ultimately enhance fitness. Social factors and contexts have at least two distinct reward functions.

First, viewing and encountering others is a reward on its own. Rhesus monkeys sacrifice quantities of liquid reward for viewing body parts of conspecifics, demonstrating that social images have reward value (124). Neurons in monkey parietal cortex code the reward value of conspecific's faces and hindquarters (279), although orbitofrontal and striatal neurons code these social stimuli often separately from liquid rewards (629).

Second, reward to others affects own reward processing. With benevolent exceptions ("Mother Teresa" and many other mothers), individuals hate to receive less reward than others when all other factors are equal. Disadvantageous inequity aversion typically induces a sharp, gradually declining, drop in the utility of own reward **(FIGURE 34*A*)** (324). Emotional correlates are envy and distaste for unequal or unfair outcomes. Individuals often also dislike, usually to a lesser extent, receiving more reward than others. This advantageous inequity aversion may elicit a similar

but weaker utility drop. Associated emotions are compassion, sense of fairness, guilt, dislike of inequity, positive reciprocity, group welfare, "warm glow," and maintaining personal social image (83, 149). The aversion may turn into advantageous inequity seeking (getting more than others) with competition and other advantage seeking situations associated with pride, sense of achievement, superiority feelings, and retaliation. Good behavioral tools for assessing inequity are the ultimatum game in which rejection of unfair offers assesses disadvantageous inequity aversion, and the dictator game in which the reward fraction handed to the opponent reflects advantageous inequity aversion (83, 149).

Final own expected utility in social settings EUnet can be stated generically as

$$\mathrm{EUnet} = \mathrm{EU} - \mathrm{EUsocial} \quad (23)$$

EU stands not only for income utility (*Equation 10*) but also for any utility EUnet derived from reward components (*Equations 11, 12, 13, 18, 21*, and *22*). EUsocial is derived from the difference between own value x and value x_o received by the opponent(s), weighted by disadvantageous (α) and advantageous (β) inequity coefficients in analogy to a popular model (150), resulting in

$$\mathrm{EUnet} = \mathrm{EU} - \alpha * \max\left[(x_0 - x), 0\right] - \beta * \max\left[(x - x_0), 0\right] \quad (23A)$$

where α and β are disadvantageous and advantageous inequity coefficients, respectively. Alternative accounts focus on reciprocal "fairness weights" which enhance own reward value when being nice to a nice opponent and reduce own value when being mean to a mean opponent, thus stabilizing cooperation and disfavoring unsocial behavior (442). Both models suggest that reward to others has appreciable value for the observer. Although condensing social reward value into a common value variable is tempting and would help to conceptualize decisions, nonvalue factors such as strategy may importantly influence decisions (50, 150, 151).

Chimpanzees and rhesus, cebus, and marmoset monkeys show prosocial tendencies and actively observe rewards in conspecifics (77, 123, 359). Cebus show disadvantageous but no advantageous inequity aversion (69). Rhesus prefer receiving own reward alone over both animals receiving the same reward, suggesting advantageous inequity seeking (negative β of *Equation 23*), and they prefer seeing conspecifics receive reward over nobody receiving reward, suggesting disadvantageous inequity seeking (negative α) in this setting (23, 89). Disadvantageous inequity reduces the effort cebus are willing to spend (612). Many of these social effects may depend on the relative social positions of the monkeys within their group and would merit further investigation. These social tendencies seem simplistic compared with those of humans but may constitute basic building blocks for social encounters and exchanges.

Reward neurons in monkey orbitofrontal cortex and striatum process primarily own rewards in social settings, whereas neurons in anterior cingulate cortex distinguish between own and other's reward or sense primarily conspecific's reward (**FIGURE 34*B***, *left*) (23, 25, 89). Striatal reward neurons distinguish between the social agents whose action leads to own reward (**FIGURE 34*B***, *right*) (25). These neurons are only active when either own action or the other's action results in own reward, and many of them do not show this activity with a computer instead of a monkey opponent. Neurons in medial frontal cortex show activations during observation of behavioral errors of conspecifics, sometimes together with observation of reward omission (647). Some premotor mirror neurons distinguish between reward and no reward irrespective of who is receiving it (78). These neuronal signals mediate the distinction between own and others' rewards and actions and thus convey basic components of social reward function. When testing social competition, reward neurons in prefrontal cortex differentiate between competitive and noncompetitive video game performance (234). In humans, disadvantageous inequity reduces, and advantageous inequity activates, ventral striatal reward responses (165), reflecting α and β of *Equation 23A* (the coding direction may reflect different signs of the two coefficients or different neuronal coding slopes). Taken together, social reward neurons code fundamental components of competition and cooperation.

10. Multiple reward attributes

Single rewards come seldom with a single attribute. Attributes include income utility, cost, delay, risk, and social interaction quantified by *Equations 9-23A*. Their aggregate subjective reward value can be condensed into a single variable called total utility. This has advantages. First, extracting the variable once from the multiple reward attributes and then using it for choices would save the decision maker computing time in crucial moments and thus enhance evolutionary fitness, even if occasional attribute changes require partial recalculations. Second, the brain could transform the condensed neuronal value responses into signals for specific decision variables for competitive decision mechanisms such as winner-take-all (see below).

Total utility EUtotal of a single reward with multiple attributes can be derived from a combination of attributes, each with their own expected utility derived from likely nonlinear and possibly nonmonotonic utility functions

$$\mathrm{EUtotal} = \mathrm{EU} + f_i * \mathrm{EUstate} + f_2 * \mathrm{EUcxt} - f_3 * \mathrm{EUcost} - f_4 * \mathrm{EUdiscount} - f_5 * \mathrm{EUrisk} - f_6 * \mathrm{EUref} - f_7 * \mathrm{EUsocial} + \mathrm{INTER} \quad (24)$$

where f_1 to f_7 are weighting coefficients reflecting the different contributions of each reward attribute. In some cases, the attributes can be so closely linked to individual rewards that the total utility u(total) of a reward can be directly derived from adding or subtracting their utility u(att) to the income utility u(m)

$$\text{u(total)} = \text{u}(m) - \text{u(att)} \quad (24A)$$

Establishing a full probability distribution from u(total) of all rewards would allow computation of EU with *Equations 9* or *10* that amounts to the same EUtotal as stated in *Equation 24*.

Take the example of a hamburger in a pub and apply *Equations 10, 11, 12, 13, 18, 21, 22*, and *23*. Its expected utility EU is defined by the probability distribution of the utilities of the slightly varying hamburger sizes u(burger). My hunger enhances EU by EUstate, and the familiar pub context associated with food and drink adds to the burger's attraction with EUcxt. However, the burger does not come for free (EUcost) and takes a moment to cook because of a busy kitchen, subjecting it to temporal discounting (EUdiscount). Burger quality varies, to which I am averse, thus reducing its EU by EUrisk, although it is still the best food in the pub, which puts its EU above a mean reference and adds EUref (in a gourmet restaurant it would have lower rank and thus lose EUref). When the burger finally arrives, it is smaller than my neighbor's and thus elicits disadvantageous inequity aversion, but better than my dieting other neighbor's salad, inducing mild advantageous inequity aversion, which both reduce the burger's EU by EUsocial. Some of these attributes are known to interact which is captured summarily by INTER. For example, smaller rewards are discounted steeper (lower EUdiscount with smaller EU) (277) and larger stakes increase risk aversion (lower EUrisk with larger EU) (152, 630).

11. Multiple rewards

Most rewards are composed of several individual reward objects whose values add up and may interact. Our hamburger meal is composed of the burger with its calories and taste, a tomato salad with taste and appealing visual aspects, and a pint of ale with water, calories, taste, and alcohol, thus totaling eight individual rewards. However, ale is sometimes poorly pulled (not in my pub), which would constitute an aversive component that would need to be subtracted from the positive components to obtain a summed final reward. If utilities of several rewards are assessed separately on a common scale, they can be weighted and added up to a summed utility, with possible interaction (INTER)

$$\text{EUsum} = \sum_i (f_i * \text{EUtotal}_i) + \text{INTER}; \quad i = 1,\ n \text{ rewards} \quad (25)$$

with f_i as weighting coefficients. Each of the rewards is likely to have its own saturation dynamics. INTER models multisensory integration as interaction that can make aversive taste or odor in some, usually small quantities add to reward value, rather than subtract from it, like pepper on meat, spicy mustard on sausage, or quinine in sugary fizzy drinks.

Equation 25 can be used for assessing the value of an otherwise unquantifiable reward on a scale defined by a common reference reward. For example, in choices between [juice plus picture] versus [juice alone], the value of the picture is reflected by the sacrificed amount of its associated juice to obtain choice indifference (124). Punishers can be included into *Equation 25* where they reduce EUsum. They constitute negative value but not economic cost, as they do not reflect energetic, temporal, or monetary expenditures. Behavioral choices of monkeys reveal the value summed from rewards and punishers compatible with *Equation 25* **(FIGURE 11*A*)** (160).

With the specification of final utility EUsum, the reinforcement *Equations 10A–D* can be restated as

$$\text{UPEsum}(t) = \lambda(t) - \text{EUsum}(t) \quad (26)$$

$$\text{EUsum}(t+1) = \text{EUsum}(t) + \alpha * \text{UPEsum}(t) \quad (26A)$$

$$\text{UTDPEsum}(t) = \left[\lambda(t) + \gamma \sum \text{EUsum}(t)\right] - \text{EU}(t-1) \quad (26B)$$

$$\text{EUsum}(t+1) = \text{EUsum}(t) + \alpha * \text{UTDPEsum}(t) \quad (26C)$$

Analogous definitions can be made for utility prediction errors of multiple attributes of single rewards by replacing EUsum by EUtotal of *Equation 24*. With multiple rewards and reward attributes, summed, single prediction errors of *Equations 26* and *26B* would not require separate computations of utility prediction error for every reward and attribute. Such prediction errors can be used by economic decision mechanisms for straightforward EU updating by standard reinforcement rules.

Alternatively, prediction errors may be computed from separate, possibly multi-attribute, rewards that are added up in a weighted manner, in analogy to *Equation 25*

$$\text{UPEsum}(t) = \sum_i \left[f_i * \text{UPEtotal}_i(t)\right] + \text{INTER}; \ i = 1,\ n \text{ rewards} \quad (26D)$$

$$\text{UTDPEsum}(t) = \sum_i \left[f_i * \text{UTDPEtotal}_i(t)\right] + \text{INTER}; \ i = 1,\ n \text{ rewards} \quad (26E)$$

A similar calculation is used for incorporating fictive outcomes into gamble values (329). This computation takes the prediction error of each reward into account. An analogous breakdown of prediction error computation, and hence updating, can be made for individual reward components listed in *Equation 24*.

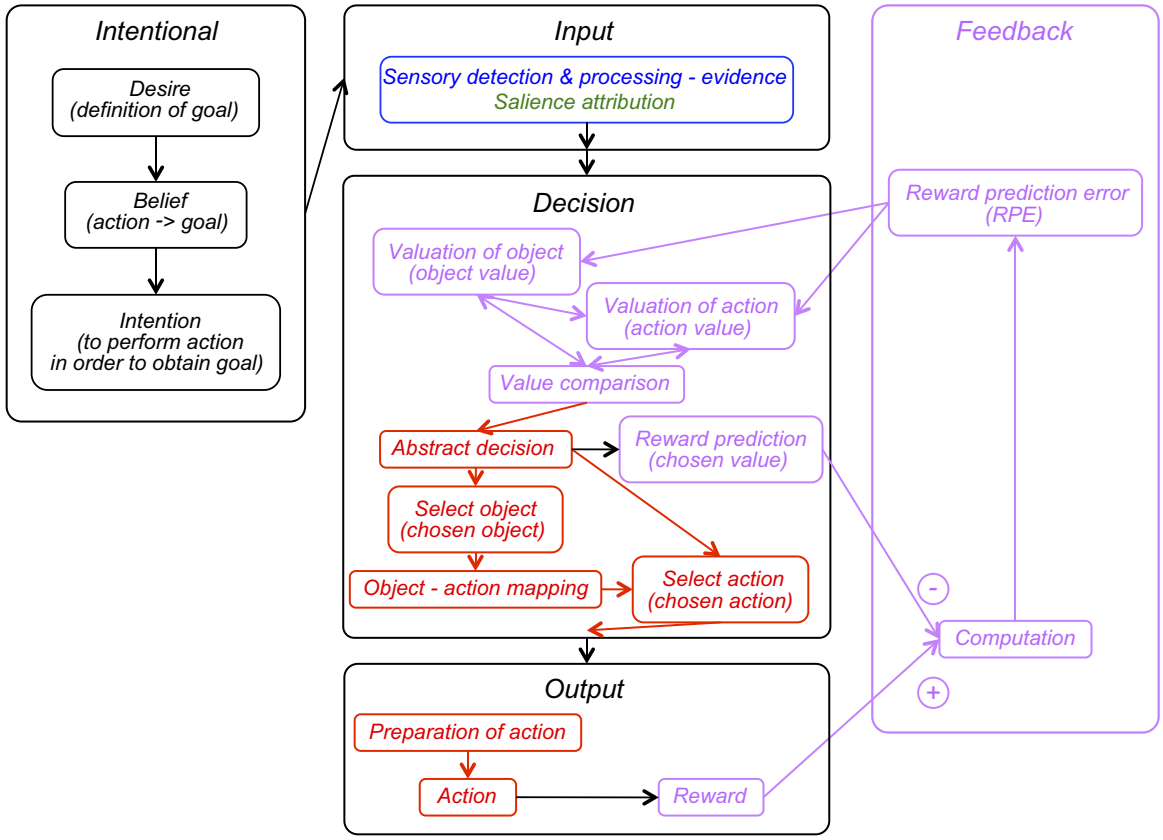

FIGURE 35. Steps and components of voluntary economic decisions. Five component processes occur in sequence, and to some extent in parallel depending on the characteristics of the decision. Decision variables are indicated in central box below their respective mediating processes (object value, action value, chosen value, chosen object, chosen action).

Given that the dopamine prediction error signal codes utility (560), the dopamine responses (*Equations 10E* and *10H*) can be restated for multiple rewards by replacing EU by EUsum

$$\mathrm{DaResp}(t) \sim \lambda(t) - \mathrm{EUsum}(t) \qquad (26F)$$

and for the temporal difference error

$$\mathrm{DaResp}(t) \sim \left[\lambda(t) + \gamma \sum \mathrm{EUsum}(t)\right] - \mathrm{EUsum}(t-1) \qquad (26G)$$

DaResp in *Equations 26F* and *26G* would apply also to utility error signals in other brain structures.

Common scale value coding is a prerequisite for applying *Equation 25* to neuronal signals and is seen in orbitofrontal cortex with different liquid rewards (405) and images of body parts (629), in parietal cortex with body part images (279), and in dopamine neurons with different liquid and food rewards (301) **(FIGURE 23, *B* AND *D*)**. Neuronal signals reflect the sum of positive and negative values from liquid or food rewards and aversive liquids or air puff punisher in monkey dopamine neurons **(FIGURE 11*D*)** (157, 160) and anterior cingulate cortex (10), and from odor rewards in human orbitofrontal cortex (190). Compatible with coding negative value as component for *Equation 25*, some frontal cortical neurons are depressed by losses of gained rewards (532). Ideally, neuronal investigations would test EUsum with all constituent components, although this is impractical and experimenters usually investigate only a few of them at a time.

D. Economic Decision Mechanisms

1. Component processes of decisions

In a highly simplified scheme, economic decisions may involve five component processes **(FIGURE 35)**. The initial intentional component comprises the desire of obtaining a reward (*left*). This emotion is based on the knowledge, or at least a hunch, that there is a reward that is worthwhile to pursue. With a belief that an action can be attributed to the reward, an intention can be formed to perform an action to get the reward. Thus the reward becomes the goal of the intentional action. In the practicalities of laboratory experiments, these processes can be driven by explicit, temporally specific stimuli indicating the availability of rewards or arise spontaneously by processes internal to the decision maker based on environmental information. The desire to get a

beer may be driven externally by the sight of a pub or internally by the heat of a summer day.

Once the intentional stage has been completed, the inputs to the decision mechanism are processed (**FIGURE 35,** *top*). Perceptual decisions require stimulus detection and then evidence accumulation for identifying the sensory reward component, tracking the object and assessing its associated salience components (**FIGURE 1,** *left* and *middle*). Correct identification of each reward option is the basis for choosing the best one. For example, perceptual decisions identify motion direction from the degree of dot motion coherence; the percentage of correct identification translates into reward probability (134, 389).

The perceptual stage is followed by valuation of the individual reward objects (**FIGURE 1,** *right*) or, depending on the characteristics of the decision, by valuation of the actions required to obtain each reward object. Valuation comprises the immediate identification or gradual accumulation of value evidence, similar to the accumulation of sensory evidence in perceptual decisions. The process may either parallel the gradual identification of the object or action or start only after they have been completely identified. The decision stage (**FIGURE 35,** *middle*) begins with object and action valuation and comprises the selection of the best reward by comparing instantaneously or gradually the values of the available objects or actions. Valuation and value comparison may evolve partly in parallel (double pink arrows). Purely sensory and motor aspects no longer play a role, unless they affect value, such as effort cost (*Equation 13*). Following valuation and value comparison, the abstract decision specifies the result of the process. It concerns only the decision itself and leads to three selections: the winning object, the winning action, and the prediction of the reward value extracted from the winning object values and action values. If the decision primarily specifies the winning object, subsequent object-action mapping determines the action required to obtain the reward object.

Obtaining the selected object and performing the selected action requires motor decisions for preparing and executing the necessary action (**FIGURE 35,** *bottom*), as every decision will ultimately lead to an action for acquiring the chosen reward. The quality of motor decisions determines the efficacy of the economic decision process. Decision makers want to get the action right to get the best reward. In cases in which different possible actions have the same cost and lead to the same reward, motor decisions may become independent of economic decisions. In these cases, the choice of the particular action may depend on noise or on motor exploration. Apart from equivaluable actions, it is unclear how much motor decisions can be independent of economic consequences. If actions are chosen for their own sake, they have intrinsic reward value and thus are economic decisions. After experiencing the selected reward object, its value is compared with the value predicted during the decision process (**FIGURE 35,** *right*). The resulting prediction error is conveyed to the valuation process in the input stage where it serves to update object values and action values.

The scheme of **FIGURE 35** should not suggest strictly sequential processing of decision variables that transitions from sensory identification via value assessment to decision-making. Real life situations are often characterized by noisy evidence, unstable values, moving objects, and changing actions and thus are likely to engage several of these processes in parallel. Furthermore, dopamine, striatum, amygdala, frontal, and parietal neurons show not only hugely different but also considerably overlapping reward valuation and decision activity. Several arguments suggest nonsequential processing of evidence, value, and decisions. First, dorsolateral frontal and posterior parietal neurons are involved in spatial movement processes but also show considerable reward value coding **(FIGURES 20*E* AND 21)** (313, 381, 433, 627). Second, ramping activity for evidence accumulation is the hallmark of cortical perceptual decisions but occurs also in subcortical structures during reward expectation and valuation (18, 40, 215, 221, 260, 523). Third, abstract decision coding and chosen action coding overlaps with reward valuation in subcortical structures, including amygdala (188) and striatum (79, 275, 306). Although the different processes may involve different neuronal pools within the same brain structures, the data nevertheless question a strictly sequential processing scheme and suggest more interactive and overlapping processing of evidence, value, and decision-making within the different structures and through subcortical loops.

In addition to many nonvalue factors that determine economic choices (see above), even purely value-based decisions may not involve the complete or correct consideration, computation, or comparison of values. A first important deviation from proper value processing is due to noise. Noise can be derived from uncertain sensory evidence (experimentally modeled, for example, by partly coherent random dot motion), varying salience attribution, imprecise estimation of economic value (economic noise, for example, when estimating probabilities from changing frequencies, or when deriving value from these probabilities), and noisy learning constants inducing unstable value predictions. Except for sensory evidence, which is external to the brain, the noise results from neuronal noise in sensory receptors and subsequently engaged neurons. Ways to deal with noisy information are averaging out the noise and accumulating the evidence over time. A second deviation from proper value processing occurs with exploration. Options that were previously suboptimal might have improved in the meantime and should better be recognized to prevent missing the best options and ensure utility maximization in the long run. Exploration is captured by ε-greedy and softmax functions (575). A single parameter models the proportion

of exploration and dominated choices (higher ε and softmax "temperature" for more exploration). Thus utility maximization involves a healthy mix of exploitation (choosing known best options) and exploration (choice of dominated but potentially better options). The proportion of exploration should be fine tuned to the dynamics of the environment to result in maximal reward. It should be higher in volatile (higher ε or temperature) compared with more stable situations (lower ε or temperature). A third deviation from proper value processing occurs with satisfying when individuals fail to consider all available options and choose only from a subset of many options that seem to satisfy their immediate desires (85, 545). Individuals may stop searching for higher value and thus make suboptimal choices. However, in some cases, the cost of considering all options may be high and reduce substantially the net benefit (*Equations 13–15*), in which cases satisfying may constitute the optimal behavior. A fourth deviation from proper value processing may be due to adaptive value processing that includes inaccessible and thus irrelevant options. In these cases, irrelevant alternatives do affect option values and may make less valuable options appear more valuable and direct choices towards them. The common result of the various forms of incomplete value consideration may be selection of suboptimal, dominated options whose values are lower than those of the best option, a behavior that compromises utility maximization.

2. Decision variables

A decision variable is what the decision maker tries to control and use to achieve the goal. It is the crucial independent variable driving the decision process. The basic decision variable in economic choices is subjective value and, more specifically, formal economic utility. The basic assumption in all economic decision theories is that decision makers aim to maximize utility. Utility is derived from several attributes including reward magnitude, probability, motivational state, context, cost, delay, risk, reference, and social interaction, as stated in *Equations 9–25* above. This notion of decision variable differs from the more technical definition that includes all sources of inputs to decision rules and mechanisms (185).

An additional definition of decision variables derives from the specific decision mechanism that serves to control them. Decision variables should be appropriate for this mechanism. Economic decision variables constitute the inputs to the decision mechanism and reflect the value of each option irrespective of the actual choice (**FIGURE 35,** *top*). The value is expressed as formal economic utility. It concerns specifically the value of a reward object (object value) and the value obtained by an action (action value). Although the decision process cannot change what is on offer, it maximizes the value by selecting the best object or action from the existing inputs (**FIGURE 35,** *middle*). This process requires sensory evidence for identification of each option as prerequisite for subsequent valuation of the options. Sensory evidence itself is not a decision variable in economic decisions, as it is imposed by the environment, and controlling it would not necessarily lead to the best reward. Furthermore, decision variables are closely related to the outputs of the decision process. The outputs controlled by the decision maker concern the reward value predicted from the decision (chosen value), the object that conveys that value (chosen object), and the selection of the valuable action (chosen action). Preparation, initiation, and execution of the action for obtaining that value are downstream processes (**FIGURE 35,** *middle* and *bottom*).

The value in the decision variables is rarely innate but acquired and updated using various forms of learning, in particular Pavlovian processes, operant habit learning, and operant goal-directed behavior, as described above. Through these three forms, objects and actions acquire formal economic utility, using model-free reinforcement learning as most basic mechanism, as stated in *Equations 10B, 10E, 26A*, and *26C*. More complex learning and updating of utility may use various forms of model-based reinforcement learning.

Perceptual decision models, which are crucial for the sensory identification of reward objects (**FIGURES 1,** *left*, and **35**, *top*), assume the gradual accumulation of evidence that needs to be extracted from noisy stimuli. Two main types of perceptual decision models vary in the way the inputs are compared with each other. Random walk, drift, or diffusion models have a single integrator with separate decision thresholds specific for each option **(FIGURE 36*A*)**. Evidences are continuously compared between options through mutual inhibition at the input level (254, 302, 447, 454, 549, 565). The resulting difference signal grows and diverges over time towards one of the decision thresholds. The decision is executed for the option whose threshold is reached first. In contrast, race models have distinct accumulators for each option, each one with its own decision threshold. The evidences grow separately until the first option reaches a specific threshold, which then generates the corresponding behavioral choice **(FIGURE 36*B*)** (327, 614, 622). Race models are appropriate for choices involving several options that are tracked separately until a final comparison can be made. Intermediate forms between diffusion and race models differ in architecture and parameter setting (55). The valuation of each option (**FIGURES 1,** ***right*****, and 35,** ***top***) may occur as soon as the perceptual decisions have been made and each reward object has been identified. In other cases, the value may not be immediately apparent and requires some time to evolve into a stable representation. Only then can an economic decision variable arise. Thus a general formulation of economic decision mechanisms should include accumulation processes for sensory and value evidence.

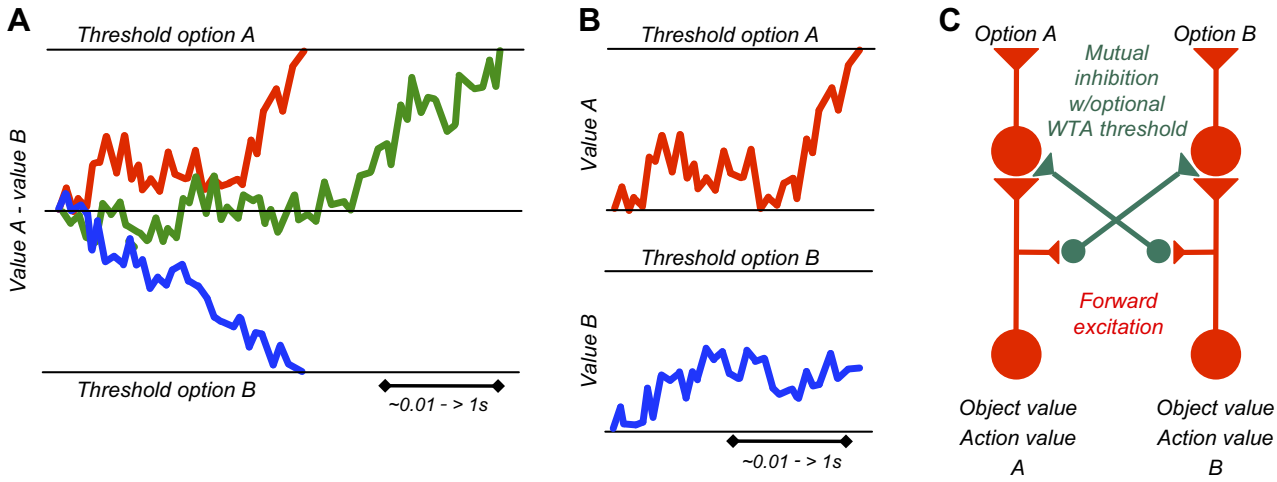

FIGURE 36. Schematics of decision mechanisms. *A:* diffusion model of perceptual decisions. Difference signals for sensory evidence or value increase in a single integrator towards a specific threshold for one or the opposite choice option (red, blue). Later threshold acquisition results in later decision (green). Time basis varies according to the nature of the decision and the difficulty in acquiring sensory evidence and valuing the options. *B:* race model of perceptual decisions. Separate signals for each choice option increase in separate integrators towards specific thresholds. The option whose value signal reaches the threshold first (red) will be pursued, whereas the lower signal at this point loses (blue). *C:* basic competition mechanism. Separate inputs for each choice option (*A*, *B*) compete with each other through lateral inhibition. Feedforward excitation (red) enhances stronger options, and mutual inhibition (green) reduces weaker options even more, thus enhancing the contrast between options. This competition mechanism defines object value and action value as input decision variables. For a winner-take-all (WTA) version, a threshold cuts off the weaker of the resulting signals and makes the stronger option the only survivor.

The basic mechanism of the decision process is competition between independent options and underlies a large variety of decision models (55, 56, 441, 585, 623). It would mediate the on-going comparison and divergence of evidence in the diffusion models **(FIGURE 36*A*)**, achieve the final comparison between options in the race models **(FIGURE 36*B*)**, or constitute a decision mechanism on its own when evidence is immediate and accumulation negligible. The minimal model comprises two inputs that map onto two outputs while inhibiting each other's influence **(FIGURE 36*C*)**. Through forward excitation coupled with mutual lateral inhibition, the stronger neuronal signal becomes even more dominant by not only inhibiting more the weaker signal but also by being less inhibited by the weaker input. The mechanism amplifies the graded differences between the inputs, analogous to lateral inhibition of sensory systems, and, with various alterations, forms the basis for competition in a wide variety of diffusion and race models for perceptual and motor decisions (55, 56, 441, 585, 622, 623) and may also apply to economic decisions. Recurrent excitation would generate gradually increasing evidence accumulation in components of the network (622, 623). An additional threshold produces a winner-take-all (WTA) mechanism by removing the weaker signal and turning the graded difference into an all-or-none output signal that reflects only the value of the strongest option or consists of an all-or-none decision signal for the winning option. This comparative mechanism provides definitions for the major decision variables.

Neuronal decision signals should reflect the decision variables defined by the decision mechanisms. The art is to identify formal, biologically plausible decision models that employ the mechanisms defining the decision variables and are implemented with identifiable neuronal activities during various trial epochs **(FIGURE 20, *A* AND *D*)**. The activities concern the initial accumulation of evidence, implemented by gradually increasing ramping activity in perceptual decisions (**FIGURES 35, *top*, and 36, *A* AND *B***), and the subsequent valuation of the options. The central competitive process and its outputs (**FIGURES 35,** *middle* and *bottom*, and 36*C*) are reflected in distinct neuronal activities coding the input decision variables of object value (405) and action value (500), the abstract decision output (188), and the chosen value (405), chosen object (38), and chosen action (543). Updating of decision variables via prediction errors occurs globally via dopamine neurons and locally through specific groups of non-dopamine reward neurons (**FIGURE 35,** *right*). Neuronal decision signals are typically investigated in choice tasks, although basic processing aspects may be studied in imperative, forced-choice trials, which allow to assign neuronal coding to individual choice options and to predictions from a single stimulus. The following sections are devoted to these descriptions.

3. Evidence and valuation

The initial stage of the decision process concerns the rapid or gradual acquisition of evidence and the valuation of the

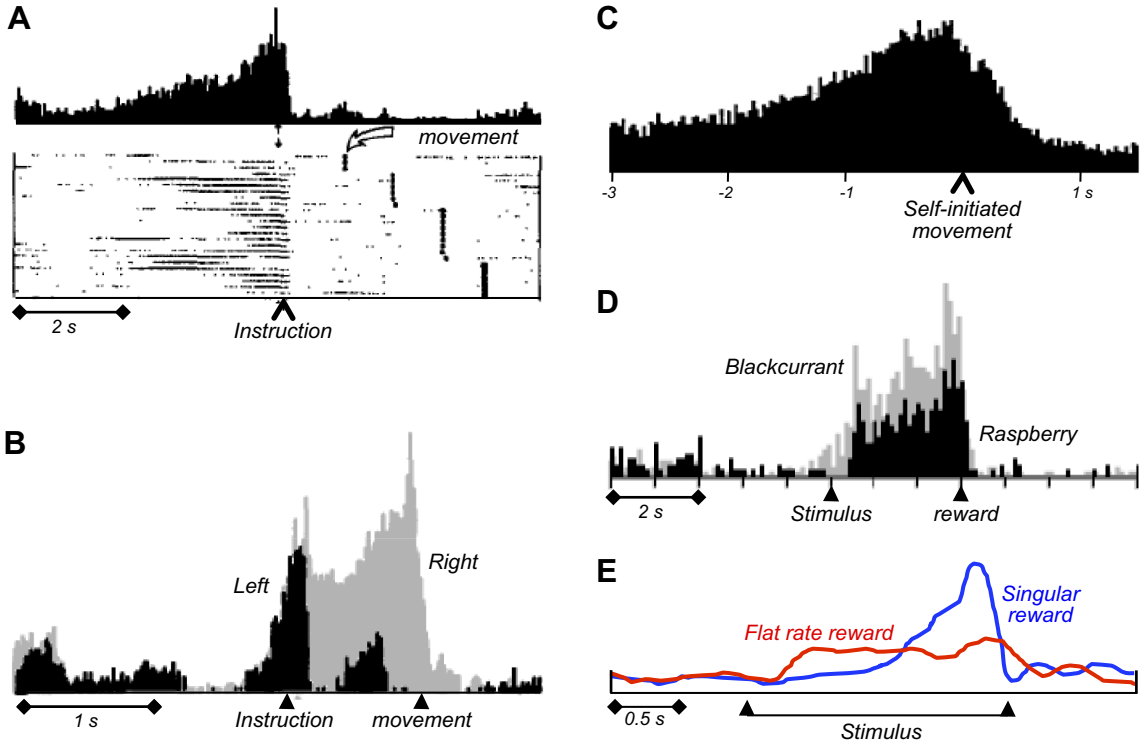

FIGURE 37. Neuronal ramping activity preceding stimuli, action, and reward. *A:* gradual activity increase during the expectation of an initial visual instruction stimulus in premotor cortex neuron. Open arrow points to movement triggering stimulus. [From Mauritz and Wise (350), with kind permission from Springer Science and Business Media.] *B:* gradual increase of left-right differential activity during movement preparation in premotor cortex neuron. Activity terminates just after the movement triggering stimulus and before the movement. Left (black) and right (gray) refer to target positions. [From Kurata and Wise (298).] *C:* ramping activity preceding self-initiated movements in striatum neuron. Activity begins gradually without external imperative stimuli and terminates with movement onset. [From Schultz and Romo (528), with kind permission from Springer Science and Business Media.] *D:* differential reward expectation activity in striatum neuron. Activity is lower in anticipation of raspberry juice (black) than blackcurrant juice (gray). [From Hassani et al. (205).] *E:* reward expectation activity in amygdala neuron reflecting instantaneous reward probability. Activity ramps up steeply before singular reward occurring at predictable time after stimulus onset (increasing reward expectation), but shows lesser increase before reward occurring pseudorandomly during stimulus (flat reward expectation with flat occurrence rate). [From Bermudez et al. (40).]

identified options (**FIGURE 35**, *top*). Acquisition of evidence takes time, in particular when the evidence itself is noisy. Neurons in many brain structures have the capability to bridge time gaps and accumulate information through persistent activity that may ramp up to future events. Ramping activity is one of the major neuronal mechanisms underlying decisions. This form of neuronal activity concerns sensory information in perceptual decisions, motor processes in action decisions, and economic utility with all its components in economic decisions (*Equations 9–13, 16*, and *21–25*).

Ramping activity reflects a general propensity for persistent, gradually increasing activity in many cortical and subcortical neurons. It occurs without choice during several processes. During the expectation of sensory events, activity increases gradually toward predictable visual stimuli in premotor cortex (**FIGURE 37*A***) (350), prefrontal cortex (65), parietal cortex (248), and striatum (6, 18, 215, 526, 528). During the instructed preparation of eye and arm movements, activity ramps up and differentiates between movements in primary motor cortex (467), premotor cortex (**FIGURE 37*B***) (298, 491, 493, 636), frontal eye field (74, 506) [and its projection neurons to superior colliculus (147)], supplementary eye field (101, 506), supplementary motor area (491, 493), parietal cortex (109, 184), superior colliculus (379), and striatum (**FIGURE 20*F***) (526, 528). Ramping activity to a threshold occurs also several seconds in advance of internally chosen, self-initiated movements in neurons of premotor cortex, supplementary motor area, parietal cortex, and striatum; these neurons are typically not activated with externally triggered movements (**FIGURE 37*C***) (299, 311, 337, 380, 397, 491, 493, 526, 528). Similar human encephalographic ramping activity resembling the readiness potential is the basis for an accumulator decision model for movement initiation (515). During reward expectation, ramping activity occurs in orbitofrontal cortex (216, 544, 602), dorsal and ventral striatum (**FIGURES 32*C* AND 37*D***) (18, 205, 215, 523), and amygdala (**FIGURE 37*E***) (40). The anticipatory ramping activity seen with sensory events,

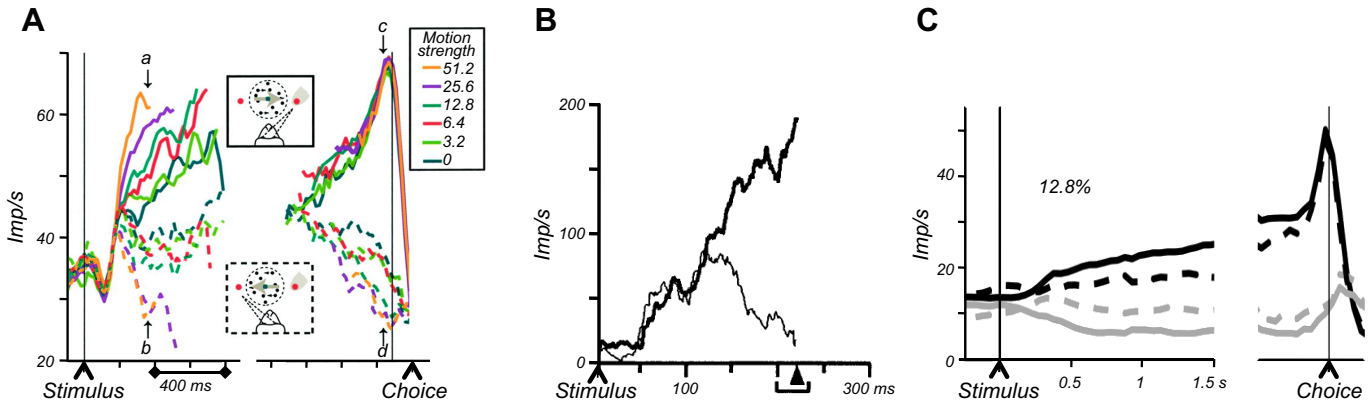

FIGURE 38. Neuronal ramping activity during perceptual decisions. *A:* ramping activity during dot motion discrimination in monkey lateral intraparietal cortex (average from 54 neurons). Continuous and dotted lines indicate saccades into and out of neuronal response field, respectively. Motion strength indicates the percentage of coherently moving dots, and thus the facility to discriminate between their direction (out of two possible directions). The buildup is steeper with higher motion coherence but ends at same height at the time of choice. Stimulus marks onset of search array (target and distractors); choice marks saccade onset. [From Roitman and Shadlen (483).] *B:* ramping activity during visual search in a monkey frontal eye field neuron. Heavy and thin lines indicate target position inside and out of neuronal response field, respectively. Stimulus marks onset of search array (target and distractors); filled arrow marks saccade onset. [From Thompson et al. (588).] *C:* average ramping activity from 104 neurons in monkey lateral intraparietal cortex reflects subjective perception of dot motion direction rather than objective motion direction (12.8% coherently moving dots). Correct trials (full line) and error trials (dashed) differentiate between saccades into and out of neuronal response field (black and gray), irrespective of actual dot motion direction. [From Shadlen and Newsome (535).]

actions, and reward may constitute a basic neuronal mechanism for perceptual decisions, economic decisions, and internal movement generation.

During perceptual decisions, primary sensory systems code evidence about physical stimulus parameters irrespective of the subject's perception and decision (120), whereas activity in secondary sensory cortex and premotor cortex reflects the animal's subjective perception (120, 121). Ramping activity occurs over several seconds in neurons in parietal cortex, frontal cortex, and superior colliculus during the gradual accumulation of noisy evidence and reaches a criterion threshold at the moment of choice. Ramping activity is absent when sensory evidence is immediate and thus may not simply reflect neuronal processing (334). Ramping activity occurs during dot motion discrimination in prefrontal cortex, lateral intraparietal cortex (LIP), and superior colliculus **(FIGURE 38*A*)** (230, 274, 483, 535); length and brightness discrimination in superior colliculus (448, 450); and visual search and visual stimulus identification in frontal eye field neurons **(FIGURE 38*B*)** (49, 587, 588). Although typically tested with two choice options, ramping activity in LIP occurs also with four options (97). The slope of the ramp buildup to criterion threshold varies in LIP and superior colliculus with the speed and difficulty of the decision derived from the coherence of moving dots **(FIGURE 38*A*)** (483), differences in reaction time (97, 270, 448, 483), and differently rewarded options (494). The height of activity at choice threshold is the same irrespective of sensory coherence and motor response time in LIP **(FIGURE 38*A*)** (483). The statistical variance of neuronal activity in LIP increases gradually and declines earlier for one option compared with the other option immediately before the action (96). The probability of accurately predicting the animal's behavioral choice from neuronal activity in LIP increases during the ramp (535), suggesting that intraparietal activity is suitable for affecting subsequent neurons involved in expressing the decision through action. Accordingly, ramping activity in prefrontal neurons changes its direction while monkeys change their decision (269). Choice accuracy depends on the starting point of the neuronal ramp but not its threshold in LIP (199). The ramping activity in perceptual choice tasks does not correlate with objective sensory stimulus parameters but reflects the subjective perception expressed by the animal's choice, as shown with errors in direction judgement in LIP neurons **(FIGURE 38*C*)** (270, 535). Ramping activity may not always reflect motor processes, as it occurs in the frontal eye field even without action (587, 588) and in LIP correlates with motion strength evidence but not action (535).

During action decisions, even when straightforward sensory signals do not require lengthy accumulation of information, ramping activity in frontal eye fields builds up to a threshold for movement initiation before saccadic choices (198) and before correctly countermanded saccades **(FIGURE 39*A*)** (507). The rate of neuronal build-up determines saccadic reaction time **(FIGURE 39*B*)** (198, 508). Neuronal activity in cingulate motor area, frontal eye fields, and LIP ramps up before monkeys change movements to restore declining reward **(FIGURE 39, *C* AND *D*)** (101, 543). During delayed action instruction, neurons in premotor cortex

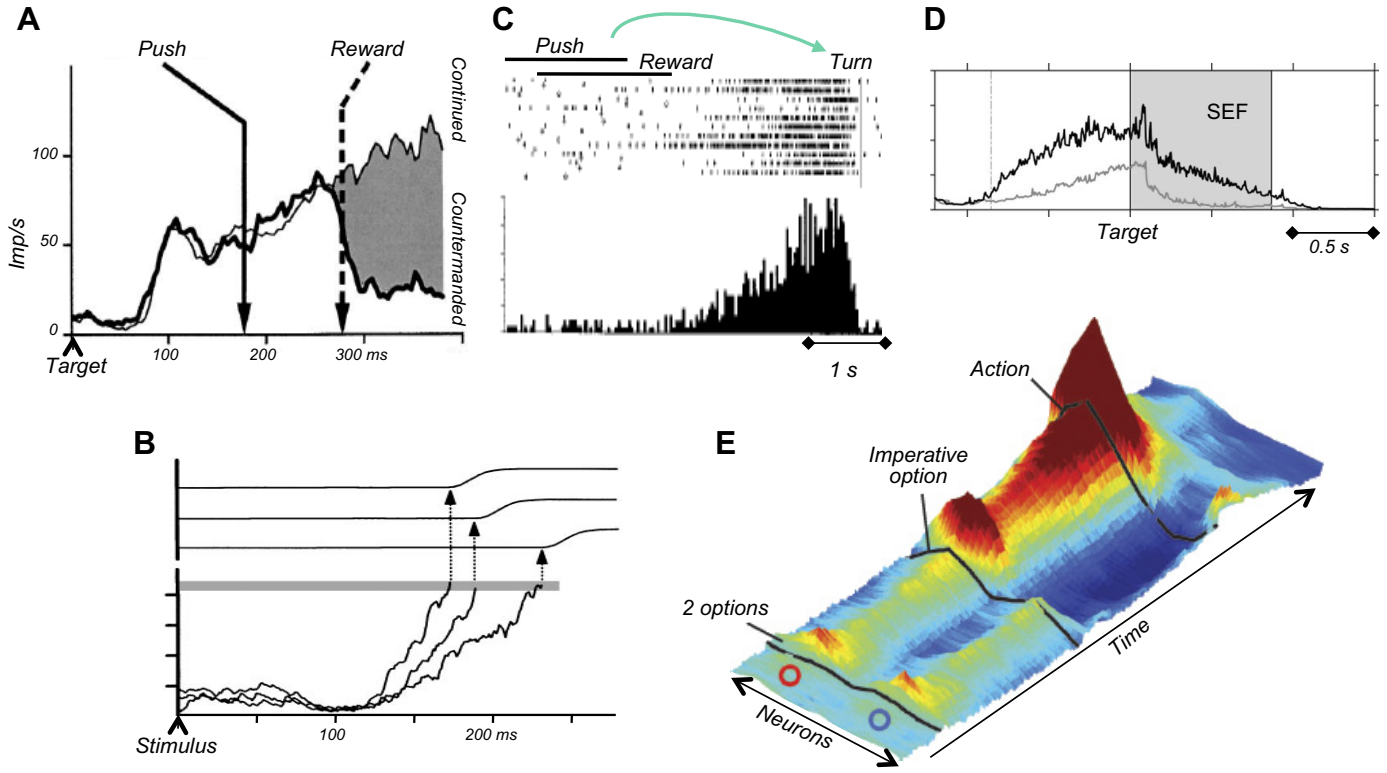

FIGURE 39. Neuronal ramping activity during action decisions. *A:* ramping activity during eye movement countermanding in a monkey frontal eye field neuron. Thin and heavy lines indicate continued and correctly stopped (countermanded) saccades, respectively. [From Schall et al. (507), with permission from Elsevier.] *B:* steeper ramping activity associated with earlier saccade choice in a monkey frontal eye field neuron. Neuronal activity has reached the same height at time of choice irrespective of slope. [From Schall and Thompson (508). Copyright 1999, Annual Reviews.] *C:* ramping activity during action decisions in monkey cingulate motor area. Upon decrease of reward amount, the monkey selects an alternate arm movement (turn) after the previous movement (push), thus restoring full reward amount. [From Shima and Tanji (543). Reprinted with permission from AAAS.] *D:* ramping activity preceding choice target reflects future choice in monkey supplementary eye field neuron. Black, free choice into neuronal response field; gray, opposite choice. [From Coe et al. (101).] *E:* differentiation of action coding in monkey premotor cortex. Neuronal population activity is initially segregated according to each action (red and blue circles) but becomes selective for final action after an imperative cue instructs the action. [From Cisek and Kalaska (99). Copyright 2010, Annual Reviews.]

show initial nondifferential activity that becomes stronger, selective, and ramps up for the action once the target is revealed **(FIGURE 39*E*)** (98). As these activities occur in motor areas, reaching the threshold may reflect the completed decision process or the initiation of action.

With economic decisions between differently rewarded options, neurons in LIP show ramping activity with noisy reward options (494). This activity likely reflects the accumulation of sensory evidence before the reward valuation rather than constituting the valuation process itself. However, LIP neurons show ramping activity also with immediately evident, non-noisy information about the reward options, such as differently colored lights at specific spatial positions **(FIGURE 40)** (571). The neuronal activity scales with the economic decision variable of fractional income and predicts the chosen action. Neurons in anterior cingulate cortex show ramping build-up towards a single threshold when animals leave a foraging patch with decaying reward value (209). Steeper ramp slopes reflect shorter reaction times for leaving the patch, as the overt choice is initiated when the common threshold is reached. These ramping activities cannot reflect noisy evidence but may constitute components of the neuronal decision process in the transition from sensory processing to reward valuation. They might also reflect associated processes such as stimulus or reward expectation or movement preparation. Nevertheless, ramping activity is not a necessary feature for economic decision activity in frontal cortex neurons (404), although its absence in a studied neuronal pool would not contradict ramping activity in other, unrecorded neurons, as cortical neurons show vastly inhomogeneous task relationships. In a probabilistic choice task with unambiguous visual symbols, parietal cortex activity reflects the economic decision variable of log likelihood ratio of probabilistic rewards (643). A potential ramp is due to averaging of asynchronous, nonramping activity. Without outright decisions, responses of amygdala and dopamine neurons reflect the

transition from initial sensory processing to reward valuation **(FIGURE 9)** (159, 422), which is considerably prolonged when the sensory evidence is noisy (389). Neurophysiological dopamine responses show a ramp with reward risk **(FIGURE 31, *C* AND *D*)** (161) but not with reward value. Striatal dopamine release ramps up before reward (237) which likely reflects presynaptic influences from reward expectation related cortical or amygdala inputs to striatum (40, 216, 544, 602) or from striatal neurons (18, 205, 215, 523) (Figures 32C and **37, *D* and *E***), but not a dopamine impulse ramp which does not occur with riskless rewards.

The morphology of ramping activity corresponds to the number of thresholds per neuron in the different decision models (56). The two-threshold drift-diffusion model assumes neuronal activity that ramps up differentially towards upper and lower thresholds for respective options **(FIGURE 36*A*)** (254, 302, 447, 565). Such activity is seen during perceptual decisions **(FIGURE 38, *A* AND *C*)** (97, 449, 483, 535) and economic decisions **(FIGURE 40)** (571). The observed gradual divergence of ramping activity in the same neuron may represent the output of an ongoing graded comparison with mutual inhibition in competing presynaptic neurons **(FIGURE 36*C*)**. The single-threshold type of decision model conceptualizes a gradual divergence of ramping activity in the same neuron. The ramp either reaches the threshold for a specific option or fades back to baseline for the alternative option **(FIGURES 36*B*)**. Such activity would also form the basis for race models in which activities from different pools of differentially active neurons race toward their individual thresholds (609, 614). Differential ramping activity is seen during the expectation of sensory events **(FIGURE 37*A*)** (6, 18, 65, 215, 248, 350, 526, 528), motor preparation **(FIGURE 37*B*)** (74, 98, 101, 109, 147, 184, 298, 299, 311, 337, 379, 380, 397, 467, 491, 493, 506, 526, 528, 636), reward expectation **(FIGURE 37, *D* AND *E*)** (18, 40, 205, 215, 216, 523, 544, 602), perceptual decisions **(FIGURE 38, *A* AND *B*)** (274, 483, 588), motor decisions **(FIGURE 39*A*)** (198, 507, 508, 587), and economic decisions **(FIGURE 40)** (571). The final step to the choice in these models may involve a graded or WTA competition between different neurons **(FIGURE 36*C*)**.

Taken together, neuronal ramping activities constitute key mechanisms in the identification of choice options from sensory evidence and may partly underlie their valuation. They reflect both the evidence that the decision maker cannot influence and the decision variables controlled by the decision maker. Ramping activities resemble statistical decision processes for accumulating stochastic information about sensory evidence (185) and rewards and follow major assumptions of decision models **(FIGURE 36, *A* AND *B*)**. The activities are widespread in the brain and reflect internal processes related to expectation of events, decisions between options, and preparation of action. As they occur also without choices, they may represent a general feature of neuronal physiology that is used for decision-making. Gradually increasing activity provides a focusing influence on downstream neurons through greater signal strength and higher signal-to-noise ratio, allowing better selection of behavioral actions **(FIGURE 36*C*)**.

4. Object value

Object value denotes the value of a specific reward object. It derives intuitively from nutrient or other survival values of rewards that are sought by humans and animals for survival. In human societies, object value is fundamental for economic exchanges of goods in which a quantity of one good with a specific value is traded against another good with a specific value. Object value is the basis for the marginal rate of substitution in economics which is the amount of *good A* a consumer is willing to give up to obtain one unit of *good B*, utility remaining constant across the exchange (341). To choose optimally, we assess the utility of each object separately, compare between them, and then select the best one. The value updating after each experienced outcome involves reinforcement learning (*Equations 10B, 10E, 26A*, and *26C*) with Pavlovian, habit, and goal-directed processes. Thus object value is defined as an input variable for competitive decision mechanisms (**FIGURES 35,** *top*, and **36*C***), in analogy to action value conceptualized in machine learning (575).

Object value has three crucial characteristics. First, it varies with the values of a reward object and, in principle, should be quantified as formal economic utility (*Equations 9–12*). Second, the value refers to one specific choice object. When choosing between several reward objects, such as a piece of meat and a loaf of bread, each object has its own and inde-

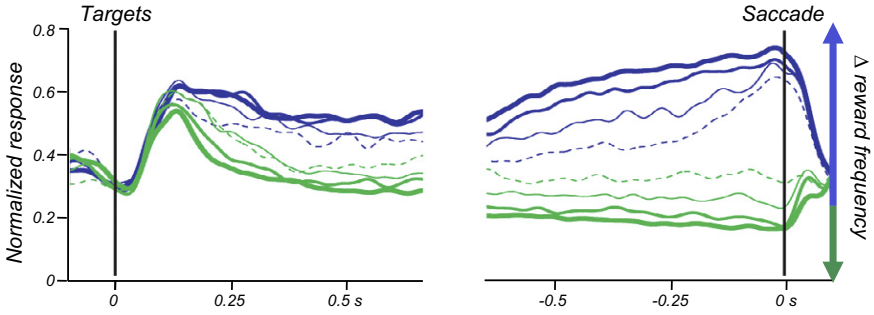

FIGURE 40. Neuronal ramping activity during economic decisions. Ramping activity in monkey lateral intraparietal cortex neurons during oculomotor matching choice between more and less frequently rewarded options (average from 43 neurons). Activity reflects the "fractional income" (ratio of chosen reward value to summed value of all options). Blue, saccade into neuronal response field; green, opposite movement. Fractional income varies between 0 (dotted lines) and 1.0 (think lines). [From Sugrue et al. (571). Reprinted with permission from AAAS.]

pendent value. "Objects" are solid or liquid rewards indicated by their appearance (color of fruit or fluid) and specific, intrinsically arbitrary stimuli associated with rewards. Different containers of the same kind of milk are examples of stimulus objects. Without being outright physical objects, events, situations and activities endowed with value have functions analogous to objects for economic decision mechanisms. The objects gain value through the animal's actual experience with the reward or from inferences based on non-Bayesian or Bayesian models of the world. Third, object value is independent of the actual choice of the object. It indicates the value of a good irrespective of whether we will imminently receive or consume it, thus complying with the notion of reward information, rather than explicit reward prediction. Economic exchanges are based on value comparisons irrespective of immediate consumption. A pound of meat has an object value of \$15 irrespective of whether I buy it now or not. Without this property, object values cannot serve as independent inputs to comparative decision mechanisms. Thus minimal tests for object value require two different reward objects, two values separately for each object, and independence from object choice.

Object value neurons process the value of one particular object irrespective of the animal's action. There would be grape juice neurons tracking the value of grape juice irrespective of the animal's choice, or banana neurons indicating how much the monkey will get if it were to climb the tree. The separate neurons tracking value for the specific objects constitute inputs for competitive decision models. In a binary decision, each input neuron, or pool of neurons, coding the value of its specific object competes with the input neurons coding the value of the other object. Hybrid subforms may show more pronounced object value coding if one particular object or action is chosen (combination with chosen object or chosen action coding defined below). To make meaningful comparisons, their signals need to vary on a common scale, both between the rewards ("common currency") and between the neurons. Neither sensory differences between rewards nor different coding ranges or slopes between neurons should affect object value signals. The model can be easily extended to three and more options as long as each neuron codes only the value of a single object. Thus object value coding on a common scale appears to constitute a suitable neuronal decision signal for competitive decision mechanisms.

Neurons tracking the value of specific reward objects irrespective of reward choice or reception are found in orbitofrontal cortex. They code selectively the value of a specific fruit juice irrespective of the monkey's choice and the required action [named "offer" value (405)] **(FIGURE 41, *A* AND *B*)** and thus do not predict the choice (404). These activities comply with the competitive formalism that requires independent coding of object value at the input **(FIGURE 36*C*)**. Orbitofrontal object value coding remains selective with three rewards (406), conforming coding specificity for a particular object. Impaired object-reward associations during choices in orbitofrontal lesioned humans and monkeys underline an orbitofrontal role in object value coding (84, 108).

In contrast, most conventional reward responses reflect explicit reward prediction or reception and thus do not have the necessary property of coding object value irrespective of the actual choice, without which they could not serve as independent inputs to competitive decision mechanisms. They reflect the actual, free or forced, behavioral choice and probably code forms of chosen value and reward prediction (see below).

5. Action value

All choices lead to movements. Whether they are ocular saccades, licking, reaching, locomotion, or speech, they all consist of muscle contractions performed to get the best value for the effort. Even verbally expressed choices, and speaking itself, involve muscle contractions (of the larynx, mouth, and hands). Machine learning and reinforcement learning, which are concerned with artificial agents moving about the world, use action value to model the agent's behavior for maximizing reward (575), like robots deciding which car part to weld first. Animals deciding between foraging patches are likely more interested in the value the action can bring them rather than considering each patch as an object. Each action leads to a reward value if it were chosen, thus the shorthand term of action value. Thus, for maximizing utility, an agent selects the action by which they achieve the highest estimated value. Pavlovian, habit, and goal-directed processes provide mechanisms for setting up and updating action value which, in principle, should be quantified as formal economic utility (*Equations 9–25*).

Actions are not only means for obtaining reward but may be themselves pleasurable and rewarding. The intrinsic reward may be added to the action value that usually refers only to the reward obtained from the action. The subjective nature of intrinsic action value emphasizes the need for quantitative behavioral assessments of often nonlinear and even nonmonotonic subjective value functions rather than inferring value from objective reward and action properties.

Like object value, action value is defined as input variable for competitive decision mechanisms (**FIGURES 35,** *top*, and **36*C***). Similar to object value, it requires three conditions. First, action value reflects reward value (amount, probability, EV, EU; *Equations 9–13*, *16*, and *21–25*). Second, value coding is specific for a particular action. The value is attached to an action and varies only for that action, such as an arm movement to the right or the left (spatial differential), an arm or an eye movement (effector differential), or going to work or vacation. Action value may arise from operant conditioning following the animal's actual experi-

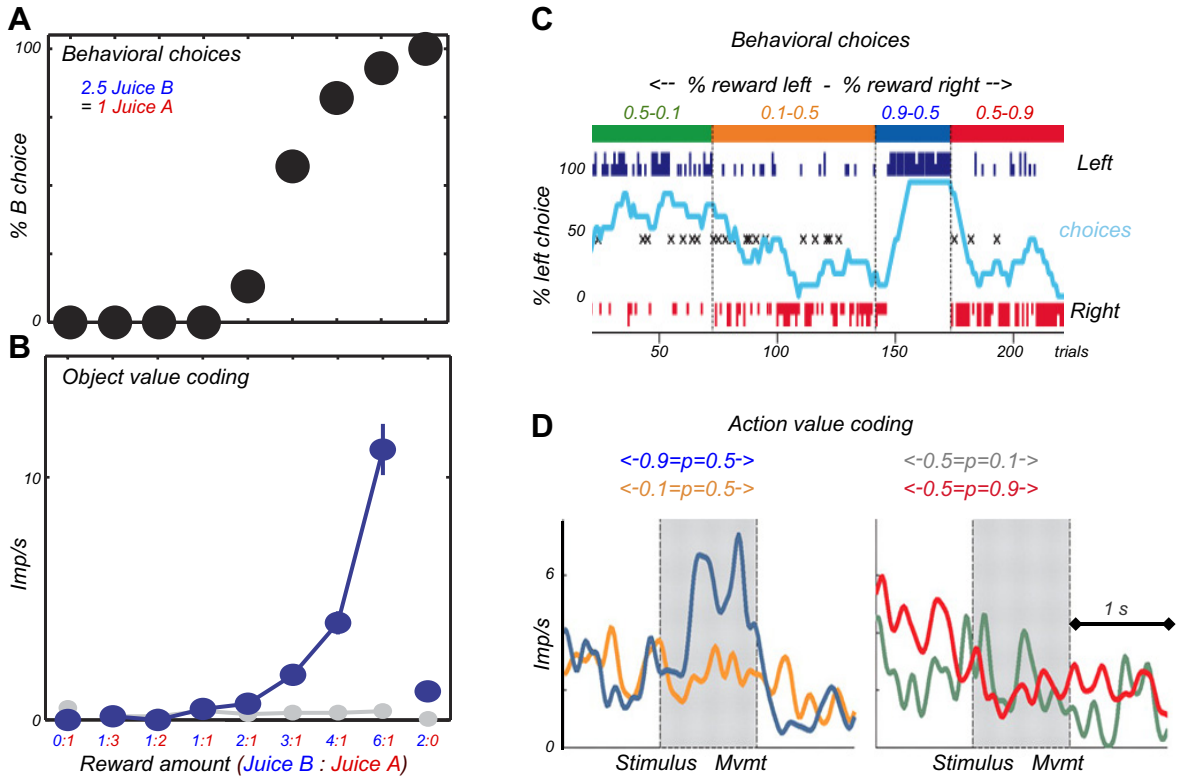

FIGURE 41. Neuronal coding of economic input decision variables for competitive mechanisms. *A:* behavioral choices between two juices that vary in magnitude. Increasing the amount of juice B (blue) increases the frequency of the monkey choosing that juice. The estimated indifference point (50% B choice) reveals that juice B is worth 0.4 units (1/2.5) of juice A. *B:* object value coding of single neuron in monkey orbitofrontal cortex during behavioral choices assessed in *A*. Activity increases with the amount of only juice B, not juice A, suggesting object value coding of reward B. [*A* and *B* from Padoa-Schioppa and Assad (405). Reprinted with permission from Nature Publishing Group.] *C:* behavioral choices between two actions that vary in reward probability. Blue and red ticks show actual choices of left and right targets, respectively. Light blue line shows running % left choices. *D:* action value coding of single neuron in monkey striatum. Activity increases with value (probability) for left action (*left panel*: blue vs. orange), but remains unchanged with value changes for right action (*right panel*), thus coding left action value. [*C* and *D* from Samejima et al. (500). Reprinted with permission from AAAS.]

ence with the reward or from inferences based on models of the world, e.g., Bayesian. Third, action value is independent of the actual action choice and the value obtained by that choice. Without this property, action values cannot serve as independent inputs to competitive decision mechanisms. Thus minimal tests for action value require two different actions, two different values for each action, and independence from choice.

Action value neurons process the value for one particular action irrespective of the animal's action. There would be left action value neurons tracking the value of a movement to the left irrespective of the animal's actual movement on that trial, and there would be separate right action value neurons. Or different neurons would respectively track the value of arm and eye movements irrespective of the animal's actual movement selection. Such separate action value tracking neurons are suitable inputs to competitive decision mechanisms that underlie utility maximization **(FIGURE 36*C*)**. Subforms may show preferential action value coding for particular chosen actions or objects. Action value signals need to vary on a common scale, both between the actions and between the neurons, to constitute comparable neuronal decision signals. Sensory and motor parameters of the action should not affect action value signals.

Neurons coding action values according to these definitions are found in monkey and rat dorsal and ventral striatum (slowly and tonically firing neurons), globus pallidus, dorsolateral prefrontal cortex, and anterior cingulate of monkeys and rats. These neurons code selectively the value of the left or right arm or eye movement irrespective of the animal's choice (**FIGURE 41, *C* AND D**) (245, 267, 275, 306, 500, 530). Action value neurons are more frequent in monkey striatum than dorsolateral prefrontal cortex (530). Action values in these studies are subjective and derived from behavioral models fitted to the choices (245, 267, 306, 500, 530) and from logistic regressions on the animal's choice frequencies (275). However, the required common scale coding is unknown. The anterior cingulate cortex is involved in action-reward mapping during choices, as lesions

there reduce preferences for more rewarded movements in humans and monkeys (84, 108).

The substantial action value coding in the striatum may reflect the pronounced motor function of this structure. Indeed, optogenetic stimulation in mice of dopamine D1 receptor expressing striatal neurons (direct pathway) induces within a few minutes behavioral preferences toward an operant touch or nose poke target associated with the stimulation, whereas stimulation of D2 receptor expressing striatal neurons (indirect pathway) induce behavioral dispreference (293). These data are compatible with the notion of striatal action value signals constituting inputs to a competitive decision mechanism located in the striatum or downstream structures.

In contrast, some reward signals reflect the explicitly predicted reward for specific actions while the actions are being planned or executed. These signals do not comply with action value coding, as they don't show the required independence from free or forced choice and action and thus are unsuitable inputs to competitive decision mechanisms (see below under "chosen value"). They code the chosen value during choices and reward prediction in choices or imperative trials. If the signals code in addition specifics of the actions they may reflect goal-directed mechanisms (see above and **FIGURE 20, *E* AND *F***).

6. Object value versus action value

The two decision variables derive from the intuition of objects having reward value that can be traded and require actions for obtaining them. The two variables may play different roles depending on the choice situation. Object value computations are likely to play a major role when values of objects change frequently and need to be tracked before choosing the required action. Once the object has been selected, its value can be directly mapped onto the action, without computing and comparing all action values. When I like to select a fruit at a new lunch place, I check the values of all available fruits (object value), and then I choose the highest valued fruit. Then I will know the action that gets me the chosen fruit (map the object to the action), without need to value each action and choose between their values. I can enjoy the feeling to soon get my beloved fruit, but that comes after the decision has been made and thus does not enter the competitive decision process. Indeed, monkey orbitofrontal neurons code the chosen value and map it onto action activity in dorsolateral prefrontal cortex to initiate the action ("good-to-action transformation," Ref. 81).

In contrast, when object values are rather stable but actions change frequently, action value would be the more appropriate decision variable. With frequent action changes, effort cost may change and should to be tracked continuously and subtracted from income value (*Equation 13*). At the time of choice, the different object values are mapped onto action values while subtracting effort cost of the currently required actions. In realistic choice situations, the progression from object value to action value may not be so stereotyped, nor would object value have primacy over action value or vice versa. Rather, object values, action values, object-action mapping, and motor plans would evolve with partial overlap depending on the choice situation. Neuronal processing of these variables and mechanisms, and the competition mechanisms at each stage, may involve separate neuronal populations in different brain structures. Indeed, orbitofrontal and anterior cingulate lesions induce differential deficits in object-reward and action-reward associations (84, 108).

7. Abstract decision

Once the comparison process has resulted in selection of the best reward object, the output of the selection process may be specified by an abstract decision signal that concerns only the decision and as such may precede the specification of the choice. Abstract decision signals code the choice in a binary, categorical manner and irrespective of value, object, or action.

Abstract decision signals are seen during perceptual decisions. They become apparent when decoupling the decision temporally or spatially from the subsequent reporting action. The signals occur without, separately from, or stronger than object or action signals in prefrontal, premotor, secondary somatosensory, and anterior cingulate cortex with vibrotactile stimulus comparisons **(FIGURE 42*A*)** (212, 312, 334, 340, 489, 490) and visual stimulus detection (360, 361). They are also seen as buildup activity in supplementary eye fields and superior colliculus during visual search (587) and random dot motion discrimination (230).

Abstract decision signals occur also in specific neurons in the amygdala that show graded reward value coding early during the trial and transition to later binary abstract decision coding **(FIGURE 42*B*)** (188). The decision signal from 1–50 pooled neurons predicts the upcoming choice correctly in 75–90% of trials, respectively, and remained predictive even with identical reward between the two options. These neurons are not activated during imperative forced-choice trials, nor do they code visual stimuli indicating the options or the subsequently chosen oculomotor actions. Abstract decision signals during economic choices in the amygdala extends its recently recognized reward function (422) to economic decision-making and challenge the view of a structure primarily known for fear responses.

8. Chosen value

Chosen value reflects the value of the specific object or action that the decision maker obtains from the choice. Its

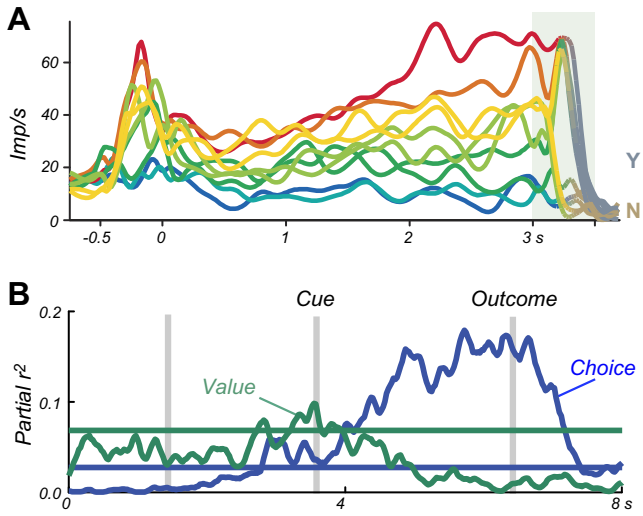

FIGURE 42. Abstract neuronal decision signals in monkeys. *A:* abstract perceptual decision coding in prefrontal cortex neuron. Initial graded frequency coding of vibrotactile stimulus (left peak) transitions to all-or-none coding of difference between two successive vibration frequencies. First vibratory stimulus begins at −0.5 s, second (comparison) vibratory stimulus begins at 3.0 s. Y and N refer to yes/no decision about the first stimulus frequency being higher than the second one. [From Machens et al. (334). Reprinted with permission from AAAS.] *B:* abstract economic decision coding during save-spend choices in single amygdala neuron. In each trial, the animal chose between saving reward with an interest or spending the saved reward. The neuron codes reward value early in the trial (derived from choice preferences, green) and later codes the actual save-spend choice (blue). Shown are time courses of the two most significant partial regression coefficients (r^2) from a multiple regression model that includes abstract save-spend choice, value (reward magnitude), spatial cue position, left-right action, and reaction time. [From Grabenhorst et al. (188).]

function is defined by competitive decision mechanisms (**FIGURES 35,** *middle*, and **36*C***). Whereas object value and action value are attached to an object or action irrespective of the choice, chosen value reflects the explicitly predicted or received reward value following the choice of that object or action. Thus chosen value reflects the output of the decision mechanism. For this important difference, chosen value should not be called object value or action value, even when it is attributed to a specific object or action. Chosen value is a decision variable, as it is controlled by the decision maker, who usually tries to maximize it (with the exceptions mentioned above). Chosen value, in principle, should be quantified as formal economic utility (*Equations 9–25*). Reinforcement learning employing Pavlovian, habit, and goal-directed processes provide mechanisms for setting up and updating chosen value.

Chosen value comes in two forms. Chosen object value reflects the value of a chosen reward object, like apple or orange, or the value of a specific stimulus predicting a particular reward. In contrast, chosen action value reflects the value of a chosen action. This distinction can be exemplified with particular reward magnitudes and probabilities. *Rewards A* and *B* are 1 ml and 2 ml of juice, respectively. *Reward A* occurs at the left in 20% of trials and at the right in 80%, whereas *reward B* occurs at the left in 60% and the right in 40% of trials. Then chosen object values are 1 ml and 2 ml for *rewards A* and *B*, respectively, whereas chosen action values are 1.4 ml for left (1 ml × 0.2 + 2 ml × 0.6) and 1.6 ml for right action (1 ml × 0.8 + 2 ml × 0.4). Most experiments do not specifically address this distinction by not using such discriminating values.

Neuronal chosen value signals reflect the value of an object or action irrespective of nonvalue attributes. These signals do not code the kind of reward (sensory aspects), sensory properties of predictive stimuli, spatial reward occurrence, stimulus positions, and required actions. In free choices between objects, specific neurons in orbitofrontal cortex code the chosen value of two or three different reward juices **(FIGURE 23, *A* AND *B*)** (405, 406). These activities reflect the estimated or experienced subjective economic value of the chosen juice, as assessed psychophysically by behavioral choices, and thus predict the choice (404). The signals scale in the same way across different rewards, thus coding value in common currency. Dopamine neurons code chosen value irrespective of action. Their value signal varies with the reward probability associated with the chosen stimulus (377). Stronger dopamine activations following conditioned stimuli predict the choice of the higher valued stimulus. Chosen value signals in the striatum show temporal discounting in choices between identical reward liquids delivered after different delays (79). Chosen value signals in anterior cingulate cortex code reward magnitude, probability, and effort, often in the same neurons (261). Chosen value signals in the supplementary eye field reflect the subjective value of objects, as estimated from certainty equivalents of behavioral choices between certain and risky outcomes (551). In imperative forced-choice trials, neurons in striatum and substantia nigra pars reticulata distinguish between stimuli predicting different reward magnitudes irrespective of sensory stimulus properties (107, 654).

In free choices between actions, some striatal neurons code chosen value without coding the action itself. The value signals vary with the reward probability associated with the chosen action and predict choice of the better action with higher activity during several task epochs (275, 306). Some striatal reward magnitude coding neurons do not distinguish between actions in imperative trials but reflect the reward value predicted from the choice (107). Chosen value signals in the striatum often occur after the overt behavioral choice, whereas action value signals typically appear before the choice (275, 306), suggesting that these chosen value signals represent the result of the decision process.

Unchosen value refers to the value of an unexperienced outcome. Whereas chosen value reflects the actual reward and is appropriate for experience-based decisions and reinforcement learning, unchosen value reflects some knowl-

edge about the world and might be more appropriate for model-based behavior. Animals benefit from the unchosen value information to improve reward gains (1, 208). Some neurons in dorsal and ventral striatum code unchosen value during intertemporal choices in monkeys (79) and during locomotor choices in rats (275). These neurons are distinct from the more frequent chosen value coding neurons in these structures. Some neurons code both chosen value and unchosen value with similar response slopes in anterior cingulate (208) and in orbitofrontal and dorsolateral prefrontal cortex (1). Thus some chosen value neurons code value irrespective of actual outcome.

Even before choosing, subjects may inspect the different options and process the anticipated value of each option. Humans show such inspectional eye movements whose frequencies and durations comply with evidence accumulation in diffusion decision models (291). It would be interesting to see whether neuronal value processing may initially reflect the value of the object or action being considered and subsequently shift to coding the chosen value. During action decisions, neurons in premotor cortex show initial activity for both actions but become selective for the final action after an imperative instruction (98, 99).

Hybrid forms of chosen value include chosen objects or actions. Corresponding neuronal signals reflect the value of the chosen reward together with sensory or motor information about the chosen object or action. If these activities occur well before the overt behavioral choice and increase towards a decision threshold, they may reflect the evidence accumulating in favor of the chosen option and thus play a role in the decision process. If the activities occur after the decision, they would constitute the outputs of the decision process and not drive the decision itself. They are occasionally referred to as object value or action value coding. However, according to the definition by competitive decision mechanisms **(FIGURE 36*C*)**, they constitute chosen value coding, as they reflect the reward value derived from the chosen objects or actions. Neuronal activity combining expected reward value conjointly with object information is only reported from imperative trials in frontal and temporal lobe neurons, as mentioned above (231, 319, 371, 394, 411), but cannot be labeled as "chosen" value due to the nonchoice task nature. Neurons coding chosen value conjointly with action are found with free choices in dorsal and ventral striatum (275, 306, 418, 479); globus pallidus (418); premotor, prefrontal, and anterior cingulate cortex (210, 532, 550, 620); and parietal cortex (433). The actions are eye or hand movements towards different spatial targets in monkeys (210, 306, 418, 433, 494, 550, 571, 620, 643) and nose pokes and whole left versus right body movements in rats (275, 479). In striatum, hybrid chosen value and action coding neurons are distinct from neurons coding only chosen value (306) or action value (306, 572). Conjoint coding exists also between unchosen value and action in orbitofrontal and dorsolateral prefrontal cortex (1). Comparable conjoint coding of value and action occurs also in nonchoice tasks (107, 135, 178, 205, 221, 243, 260, 282, 308, 313, 348, 354, 381, 427, 476, 502, 542, 606, 627), without qualifying for chosen value coding.

9. Relative value

The competitive decision mechanism for maximizing utility **(FIGURE 36*C*)** does not depend on actual values but involves comparison of the options relative to each other and is thus based on the difference or ratio of their values. Thus relative value is an important decision variable which, in principle, should be quantified as utility. Random walk-diffusion models capture the importance of relative value by assuming an early comparison with subsequent evidence growing toward specific thresholds. The mechanism for coding relative value may involve mutual inhibition between inputs that generates a graded difference between the inputs, amplified by the inhibition exerted by stronger inputs onto weaker inputs.

For binary decisions between *options 1* and *2*, the relative value can be stated using the final utility defined in *Equation 25*

$$\mathrm{REUsum} = \mathrm{EUsum1} - \mathrm{EUsum2} \qquad (27)$$

Instead of EUsum, any of the constituent utility functions defined by *Equations 9–13*, *16*, and *21–24* can be used for *Equation 27*. Most simply, REUsum may be derived from objective magnitudes $m1$ and $m2$

$$\mathrm{R}m = m1 - m2 \qquad (27A)$$

to obtain relative utility

$$\mathrm{Ru} = \mathrm{u1} - \mathrm{u2} \qquad (27B)$$

By applying a logarithmic utility function u = log (m), we obtain

$$\mathrm{Ru} = \log(m1) - \log(m2) \qquad (27C)$$

which is equivalent to

$$\mathrm{Ru} = \log(m1/m2) \qquad (27D)$$

As *Equations 8* and *9* show, reward value derives not only from reward magnitudes but also from reward probabilities. We replace $m1$ and $m2$ by probabilities $p1$ and $p2$

$$\mathrm{Ru} = \log(p1/p2) \qquad (27E)$$

Ru is a log odds ratio, also called log likelihood ratio (643). General simplifying formulations would replace objective m and p by their summed product of EV.

Another good measure of relative value is the ratio of objective values (magnitudes or probabilities)

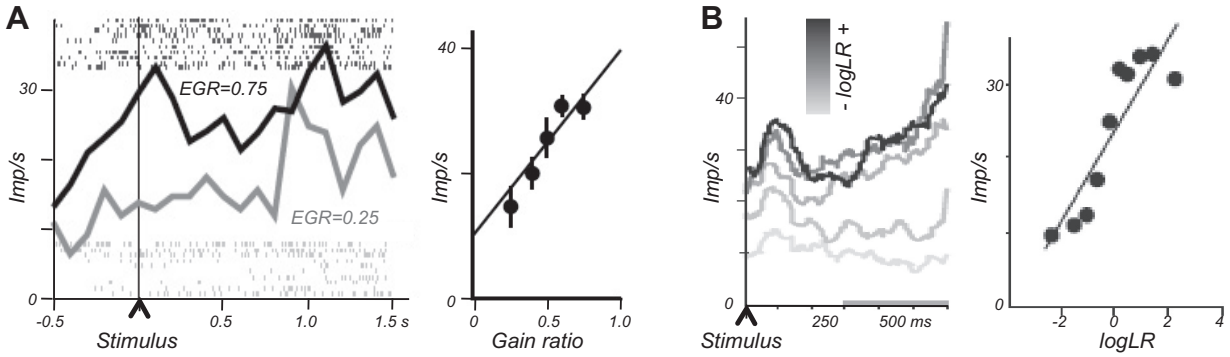

FIGURE 43. Relative value signals in monkey lateral intraparietal cortex. *A:* single neuron activity reflecting relative value during free oculomotor choice. *Left*: higher activity with higher "expected gain ratio" (EGR), lower activity with lower EGR. *Right*: linear regression on EGR. EGR denotes liquid reward volume of chosen option divided by summed magnitude of all options. [From Platt and Glimcher (433). Reprinted with permission of Nature Publishing Group.] *B:* single neuron responses increasing with the log likelihood ratio (logLR) of reward probabilities between chosen and unchosen options (choices into neuronal response field). [From Yang and Shadlen (643). Reprinted with permission from Nature Publishing Group.]

$$\mathrm{R}v = v1/v2 \qquad (27F)$$

The simple value ratio is often extended to include the summed value of all options in the denominator, called expected gain ratio (433) or fractional value (571)

$$\mathrm{RS}v = v1/\sum v_i;\ \text{for } i = 1, N;\ n = \text{number of options} \qquad (27G)$$

Reference value defined by *Equations 27-27G* applies to all forms of economic value, including object value, action value, and chosen value, and to all value functions defined by *Equations 8–13, 16*, and *21–24*. In monkeys, binary behavioral choices follow relative subjective value defined by the log odds ratio (*Equation 27E*) (643), reward magnitude ratio (*Equation 27F*) (306), or the ratio of objective chosen reward magnitude or probability over all options (*Equation 27G*) (433, 571). These measures are good predictors of choice preferences.

The difference value of *Equation 27* is analogous to reference-dependent utility (*Equation 22*), as both terms indicate relative value. Thus difference value and value adaptation serve the same function. They allow comparisons between existing options rather than requiring separate computations of the values of all options. Value ratios of the chosen option over the alternative (*Equation 27F*) or all options (*Equation 27G*) add adaptation to the spread of the reward probability distribution and correspond to divisive normalization in adaptive coding (332).

Some neurons in monkey and rat dorsal and ventral striatum, globus pallidus, and anterior cingulate cortex code difference subjective action value during free choices with eye or body movements, conforming to *Equation 27A* (79, 245, 306, 531, 572). Subjective value is derived from reinforcement models fitted to the choices or logistic regressions on choices. During temporal discounting, neurons code differences in subjective action value in dorsal striatum, and to some extent in ventral striatum (79). The discounted, subjective value is assessed from logistic regressions on intertemporal choices. Due to the relative nature of difference coding, neuronal activity varies positively with the value of one action or negatively with the value of the alternative action. True to the definition of action value, these relative value signals do not depend on actual choice. Neuronal difference signals exist also for chosen value in dorsal and ventral striatum, which take both chosen and unchosen values into account (79, 306). These activities increase with the value of one option and decrease with the alternative's value and, different from action value, depend on the actual choice. Neuronal activity in parietal association cortex reflects the reward ratio of the chosen option over all possible options (*Equation 27G*) **(FIGURE 43*A*)** (137, 433) and reaches a threshold at the time of choice **(FIGURE 40)** (494, 571). Similar parietal activity follows the increasing, logarithmic reward probability ratio between two options (*Equation 27E*) in the statistical sequential ratio test **(FIGURE 43*B*)** (643). Finally, difference signals for hybrid chosen value and oculomotor action exist in dorsal and ventral striatum (79, 306). Taken together, there are groups of distinct reward neurons coding basically every form of value decision variable in a relative way.

10. Chosen object and action

Although economic decision variables center around value, once the decision has been specified internally, the process may transfer to the overt behavioral choice without any longer involving value. Some neuronal signals in principal reward structures code the chosen object or the chosen action (frontal cortex, parietal cortex, and striatum) (**FIGURE 35,** *middle*).

Chosen object signals code the specific reward selected during the decision process or the specific visual stimulus pre-

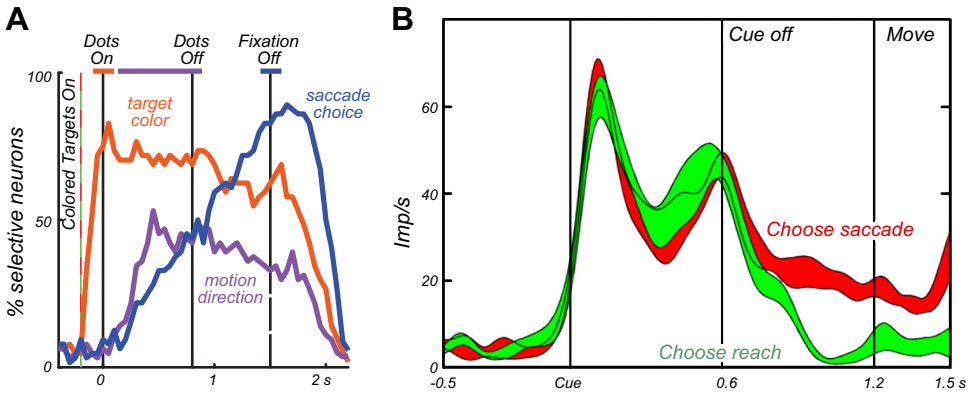

FIGURE 44. Chosen object and action signals in monkey lateral intraparietal cortex. *A:* coding of chosen object (orange color) or chosen action (blue) during perceptual decisions in population (averages from 23 neurons). In the conditional motor task, the animal saccades to a red or green dot (chosen object) depending on the direction of random dot motion. The dots are shown at different spatial positions and thus require different saccades (chosen action). Ordinate is % of significantly responding neurons for chosen object and chosen action (and dot motion direction, magenta). [From Bennur and Gold (38).] *B:* chosen action coding in single neuron. After a common onset, activity differentiates between effectors ~400 ms before action (saccade vs. reach). [From Cui and Andersen (109), with permission from Elsevier.]

dicting a particular reward. They serve to identify the chosen reward object while it is being acquired by an action. The signal does not code value and is not a simple visual or somatosensory response, as it may precede the appearance of the object. With economic decisions, chosen object signals in orbitofrontal cortex reflect different juices (405). With perceptual decisions, LIP neurons code the target color chosen for reporting the earlier, temporally distinct random dot motion direction (**FIGURE 44*A***, orange) (38). The signal is distinct from abstract decision and chosen action coded by other parietal neurons.

Chosen action signals code the specific action for acquiring the reward and may serve to prepare, initiate, and execute the necessary motor processes. These signals reflect the future action rather than reward value. They occur in cingulate motor area, anterior cingulate cortex, frontal and supplementary eye fields, and parietal cortex when monkeys change their actions after the reward for the current action declined (543), even before contacting a switch-over key (209) or before a chosen target occurs **(FIGURE 39*D*)** (101). The signals are absent or less pronounced in imperative forced-choice trials (101, 543). Neurons in LIP code the chosen saccadic action during probabilistic reward choice (433, 571), intertemporal choice (477), and dot motion discrimination (494), both during free choices and imperative forced-choice trials. In monkey and rat striatum, different neurons code chosen action from action value or chosen value during probability matching (306), locomotor choice (275), and intertemporal choice (79). Neurons in ventral striatum show much less chosen action signals than in dorsal caudate nucleus (79). Chosen action signals seem to begin earlier in striatal compared with parietal neurons and in both structures follow the subjective value signals by a few hundred milliseconds (79, 306, 477, 494). Some chosen action signals in parietal cortex are in addition modulated by chosen value (571). Thus chosen action signals occur in reward neurons close to behavioral output.

With perceptual decisions, parietal cortex neurons code the saccadic action for reporting random dot motion direction, distinct from abstract decision coding (**FIGURE 44*A***, blue) (38). Neurons in superior colliculus show chosen action signals superimposed on abstract decision signals (230).

With motor decisions, parietal cortex neurons show differential activity preceding freely chosen eye or arm movements **(FIGURE 44*B*)** (109, 509). During instructed action selection, separate neurons in premotor cortex initially code all options, but their activity differentiates and ramps up specifically for the arm movement imposed by a cue **(FIGURE 39*E*)** (98, 99). Although not reflecting free choice, the activity shows a nice transition from separate option coding to specific option coding as a general template for the progression of neuronal coding of economic decision variables.

11. Updating economic decision variables

Whereas perceptual decisions are based on sensory evidence, economic decisions require additional information about the value obtained by the choice. For meaningful decisions, this information needs to be predictive of the outcome. Choices without predictions amount to guessing. The value prediction does not derive from sensory organs but is learned and updated by error driven reinforcement learning. Its crucial error term is computed as the difference between the experienced reward and its prediction (*Equations 1, 2, 4, 5, 8A*–D, and *26-26C*).

The prediction entering the error computation derives from different sources (575). In model free reinforcement learn-

ing (460), the prediction derives only from direct experience with the values of the chosen objects or chosen actions in the past several trials. Other decision variables providing predictions, such as object value and action value, are only partly suitable for computing prediction errors because they are independent of the object or action being chosen and thus independent of the actually experienced reward. Their predictions are only useful for computing prediction errors when the objects or actions are chosen and their outcomes experienced, whereas unchosen rewards cannot enter the error computation. Thus the prediction in standard, model-free reinforcement learning derives from chosen value, which is a decision variable. In model-based reinforcement learning, the prediction incorporates information from models of the world and does not only reflect the recent experience with the outcome. The value prediction can be accurate even for objects and actions that have not recently been chosen and experienced. For example, given a model that assumes a constant sum of left and right action values, the left action value prediction can be accurate after only experiencing a right action and its outcome. Model-based reinforcement learning incorporates information beyond the experienced chosen value into the prediction and thus affects the error computation, whereas the reward is experienced as a matter of fact irrespective of model or not.

The type of prediction entering the error computation affects the form of the reward prediction error and thus the efficacy of value updating in specific learning scenarios (575). Three models are noteworthy in this respect. First, the Sarsa model applies to a range of laboratory tests in which the agent can experience all options during learning. Its prediction error incorporates the prediction derived from chosen value, which reflects the choice, but prediction from object value and action value is only valid when it derives from the actual choice. Thus chosen value neurons in striatum, orbitofrontal cortex, supplementary eye field, and anterior cingulate cortex (79, 208, 245, 261, 275, 306, 377, 405, 551) may serve as prediction inputs for the Sarsa model, and dopamine neurons code prediction errors in chosen value according to the Sarsa model (377). Second, Q learning directly approximates the optimal reward value within a given choice set. Its prediction error incorporates the prediction of the maximal attainable reward value, without taking the choice into account. Neurons in monkey anterior cingulate cortex code the prediction for the maximal probabilistic reward value that the animal usually but not always chooses (called task value) (12). Outright prediction error signals coding maximal value have not been described. Third, actor-critic models incorporate the sum of reward predictions from all options. Neurons in striatum, globus pallidus, and anterior cingulate cortex code the predicted sum (or mean with steeper slope) of reward values (79, 208, 245, 531). Taken together, the Sarsa reinforcement model has a correlate in the prediction error signals of dopamine neurons and other reward neurons that reflect predictions derived from chosen value. Future experiments might search for prediction error signals of the other reinforcement models in a wider range of learning situations.

Error signals suitable for updating decision variables are found in several reward structures. The bidirectional dopamine reward prediction error response (517) occurs with visual, auditory, and somatosensory stimuli (221, 365, 492) irrespective of action (521, 597, 618); integrates reward delay, reward risk, and different liquid and food rewards into a common subjective value signal (285, 301); incorporates model-based predictions (68, 382, 598); and reflects chosen value (377). Subgroups of non-dopamine neurons show bidirectional prediction error signals in lateral habenula, striatum, globus pallidus, amygdala, anterior cingulate cortex, and supplementary eye field (15, 36, 134, 227, 261, 275, 344, 531, 551). Some error signals in striatum code additional sensory and motor parameters (556). Neurons in cingulate cortex and supplementary eye field code bidirectional prediction errors from object value and action value to the extent of the object or action being chosen and leading to actual reward experience (chosen object value and chosen action value) (531, 550). Possible prediction error signals are also the separate, unidirectional positive and negative prediction error activations in anterior cingulate and supplementary eye field (246, 261, 551).

The updating function of the dopamine prediction error signal can be considered within the generic competitive model of decision-making **(FIGURE 45)**. Irrespective of the differences between formal decision models (55, 56, 441, 585, 623), the dopamine response would primarily update the inputs to the comparison process, namely, object value and action value that are coded during various trial epochs **(FIGURE 20, *A* AND *D*)**. The experienced and the predicted reward for the dopamine error computation likely derive from chosen value. The dopamine signal is rather similar among individual neurons and has heterogeneous effects on heterogeneous postsynaptic neurons. However, object value and action value are processed irrespective of the decision. They do not provide the necessary postsynaptic specificity to make the dopamine influence selective, which would indiscriminately update all object values and action values, including those not even experienced. However, as primary and higher order rewards occur only after an event, neuronal updating involves stimulus traces that maintain a label of the engaged synapses beyond the event and make them eligible for modification (574). Thus each object value and action value signal may leave a distinct eligibility trace that decays rapidly unless being stabilized by neuronal inputs **(FIGURE 14, *B* AND *C*)**. Neuronal activity from the specific chosen object/chosen action signal may provide selective inputs to object value/action value neurons for the same object/action for stabilizing their eligibility traces (**FIGURE 45,** *right*), whereas the lack of activity from the unchosen option would not prevent the decay (*left*). Thus the

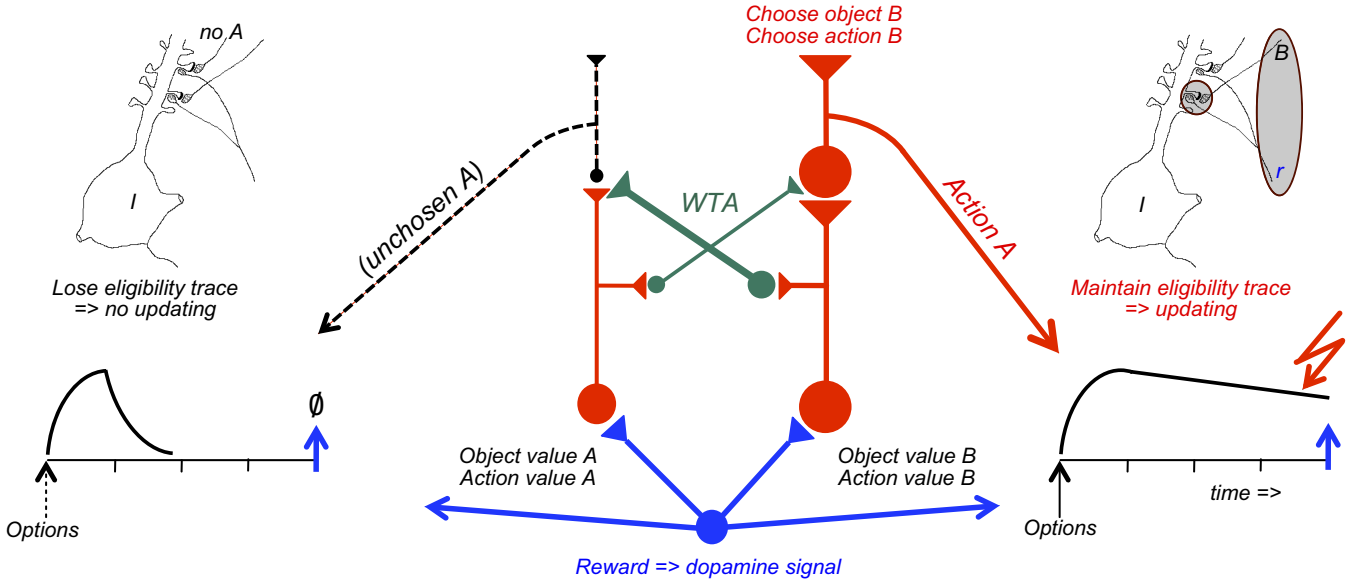

FIGURE 45. Hypothetical mechanism of dopamine updating of decision variables. Within a competitive decision mechanism, the global dopamine reward prediction error signal would act indiscriminately on postsynaptic neurons and changes their synaptic input efficacy by influencing stimulus eligibility traces. It affects only neurons coding object value or action value of the option chosen, as only their eligibility traces are being stabilized and maintained by input from neurons activated by the chosen object or chosen action (*right*), but not affect neurons whose initial eligibility traces are lost due to lack of stabilizing input from neurons not being activated by the unchosen object or unchosen action (*left*). This selective effect requires specific connections from chosen object/chosen action neurons to object value/action value neurons for the same object/action. The prediction error conveyed by the dopamine neurons derives from chosen value (experienced minus predicted reward). Gray zones at *top right* indicate common activations. The weight of dots and lines in the circuit model indicates level of neuronal activity. Dotted lines indicate inputs from unchanged neuronal activities. Crossed green connections are inhibitory; WTA, winner-take-all selection. Scheme developed together with Fabian Grabenhorst.

maintained eligibility trace reflects the output of the decision process and provides the necessary specific label for dopamine influences to act upon. As a result, the indiscriminate dopamine signal would selectively update the object value and/or action value of the chosen option, whereas object value and/or action value of the unchosen option remain unaltered and need to wait for their next selection before being updated (except in model-based reinforcement learning, see above). Thus the influences of chosen object and chosen action on the eligibility trace provide the necessary selectivity for dopamine action. As an example **(FIGURE 45)**, choice of a movement to the right and experience of the corresponding reward would lead to updating of right action value by a prediction error signal. If the right choice resulted in a higher than predicted value and thus a positive prediction error, right action value would be increased; however, if the value is lower than predicted and elicits a negative prediction error, right action value would be decreased. If the right action is not chosen, its value cannot be experienced and thus will not be updated (or might decay depending on the algorithm implemented). Taken together, within a simple comparator model of decision-making, the global influence of the dopamine error signal derived from chosen value may serve to update input decision variables for specific options via eligibility traces selectively stabilized by activity from the chosen option.

Neuronal correlates for this hypothetized dopamine influence consist of the global projection of this reward signal to most or all neurons in striatum and frontal cortex and to many neurons in amygdala, thalamus, and other structures **(FIGURE 17*A*)**. The released dopamine influences the plasticity between conjointly active presynaptic and postsynaptic neurons in a three factor Hebbian learning scheme **(FIGURE 17, *B* AND *C*)** involving striatum, frontal cortex, and other structures in which appropriate dopamine dependent plasticity is found (82, 194, 265, 294, 400, 401, 424, 461, 495, 540, 583, 642, 648). In this way, the dopamine signal could affect synaptic transmission onto striatal and cortical neurons coding object value and action value. These effects may be differential within striatal regions, as action value neurons are more abundant in dorsal compared with ventral striatum (245), whereas ventral striatum neurons are more involved in reward monitoring unrelated to action coding (245, 523). The dopamine plasticity effects may also be differential for striatal neuron types, as optogenetic stimulation of neurons expressing D1 or D2 dopamine receptors induces learning of behavioral preferences and dispreferences, respectively, possibly by updating action values **(FIGURE 19*F*)** (293). These neuronal data support the scheme of dopamine updating of decision variables **(FIGURE 45)**.

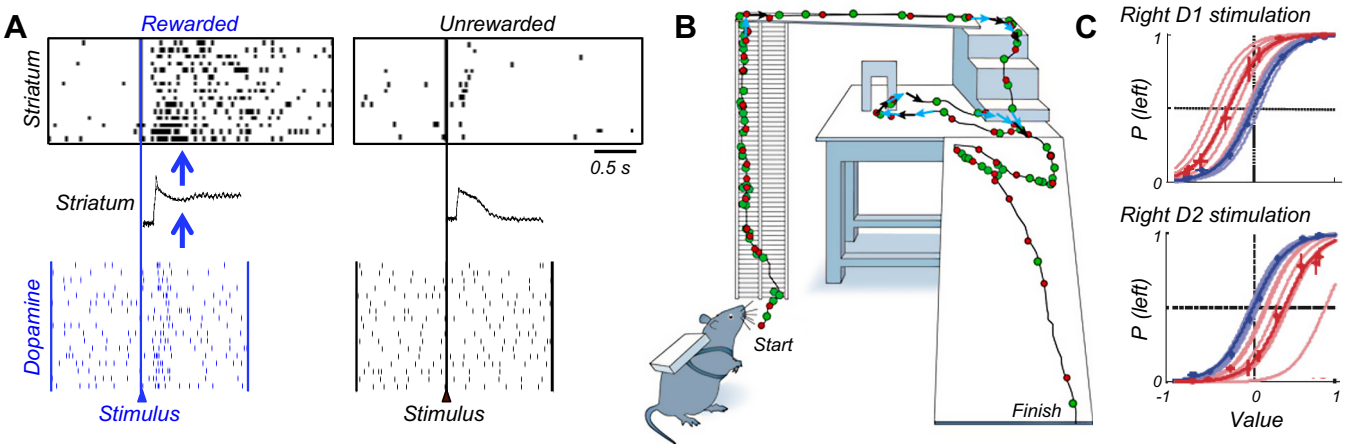

FIGURE 46. Immediate dopamine influences. *A:* hypothetical mechanism of influence of dopamine reward signal on striatal reward response. *Bottom*: a rewarded, but not unrewarded, stimulus differentially activates a dopamine neuron. [From Tobler et al. (598).] *Middle*: possible dopamine influence on striatal synaptic potentials: dopamine D1 receptor agonist prolongs the depolarization of a striatal neuron. [From Hernández-Lopez et al. (213).] *Top*: as a result of the dopamine influence on striatal depolarization, the striatal neuron responds stronger to a rewarded compared with an unrewarded stimulus. [From Hollerman et al. (222).] *B:* influence of dopamine reward signal on behavioral navigation. Electrical stimulation to the left and right somatosensory cortex of rats provides cues for turning; electrical stimulation of the medial forebrain bundle containing dopamine axons induces forward locomotion. The combined stimulation is able to guide a rat through a three-dimensional obstacle course, including an unnatural open field ramp. Colored dots indicate stimulation of forebrain bundle and somatosensory cortex. [From Talwar et al. (580). Reprinted with permission from Nature Publishing Group.] *C:* influence of dopamine reward signal on behavioral choices. Unilateral optogenetic stimulation of mouse striatal neurons expressing dopamine D1 or D2 receptors induces immediate differential choice biases (left bias for right D1 stimulation, *top*; and right bias for right D2 stimulation, *bottom*). [From Tai et al. (576). Reprinted with permission from Nature Publishing Group.]

Updating with non-dopamine error signals may be less global and more selective. These neurons likely exert focused influences on specific postsynaptic neurons through selective anatomical projections. Their error signals are more specific for the type of information they provide and for the type of postsynaptic neuron they influence. Thus they are likely to be more specific for the objects and actions and the type of neuronal value signals they update.

12. Immediate dopamine influences

In addition to affecting synaptic plasticity and learning, phasic dopamine signals exert immediate influences on postsynaptic processing and behavioral performance and choices. The anatomical basis may be the triad arrangement of dopamine synapses on glutamatergic inputs to dendritic spines of striatal and cortical neurons **(FIGURE 17*B*)** (171, 186) and convergence in striatum and globus pallidus (416, 430). The long debated focusing effect assumes that dopamine signals suppress the effects of weaker inputs to the striatum while allowing stronger ones to pass through to the basal ganglia outputs (70, 368, 594). Thus phasic dopamine signals may affect the function of existing anatomical convergence and modulate the use of neuronal connections. At the cellular level, the phasic dopamine signal has excitatory action on D1 receptor expressing striatal neurons of the direct pathway by prolonging transitions to membrane up states (depolarization) (213). In contrast, dopamine action on D2 receptor expressing striatal neurons of the indirect pathway reduces membrane up states and prolongs membrane down states (hyperpolarization) (214). In a hypothetical model of such action, the dopamine enhancement of cortical input efficacy may induce reward related activity in striatal neurons **(FIGURE 46*A*)**. This influence may affect reward processing in all forms of striatal task related activity **(FIGURE 20, *A* AND *D*)**. Impairments of dopamine transmission reveal the immediate dopamine influences. Striatal dopamine depletion reduces learned neuronal responses in striatum (13), alterations of D1 receptor stimulation affect mnemonic behavior and neuronal activity in frontal cortex (505, 616), and reduction of dopamine bursting activity via NMDA receptor knockout prolongs reaction time (650). These deficits relate well to the immediate behavioral effects of phasic dopamine stimulation. Optogenetic activation of mouse dopamine neurons, in addition to providing reinforcement, elicits immediate behavioral actions, including contralateral rotation and locomotion (271). Pairing electrical stimulation of the medial forebrain bundle containing dopamine axons with lateralized stimulation of somatosensory cortex induces forward locomotion in rats and directs the animals in sophisticated and even unnatural spatial navigational tasks **(FIGURE 46*B*)** (580). The forebrain bundle stimulation likely serves as immediate reward, whereas the cortical stimulation provides the necessary spatial information. Corresponding to the action-inducing effects of dopamine stimulation, indirect inhibition of VTA dopamine

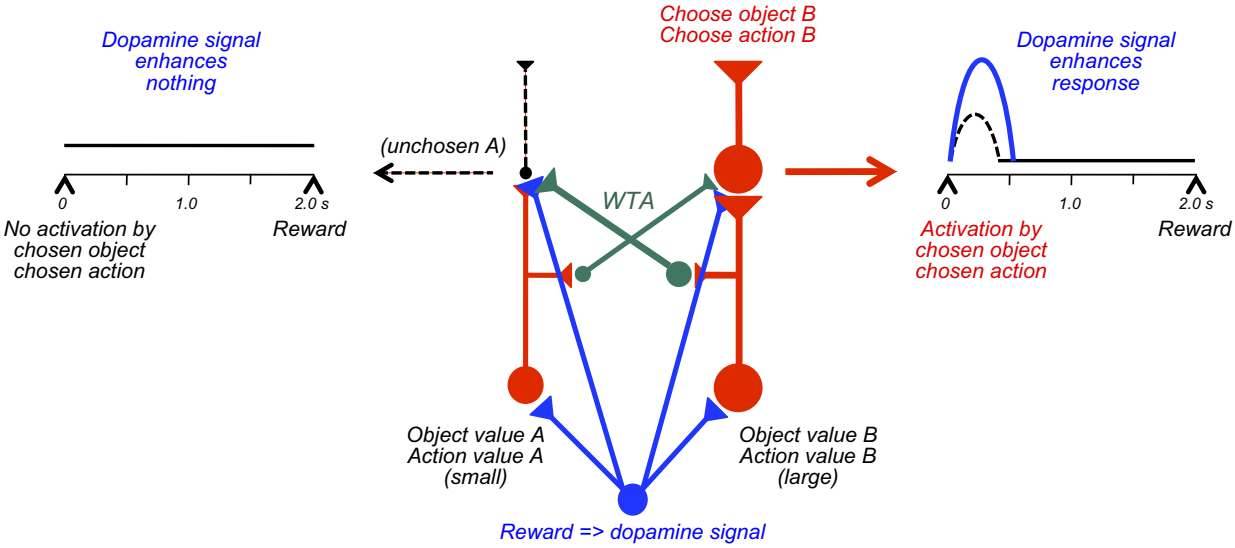

FIGURE 47. Hypothetical mechanism of immediate dopamine influence on neuronal coding of decision variables. For the basic competitive decision mechanism, the dopamine signal arises from a temporal difference (TD) prediction error in chosen value at the time of the decision. The dopamine signal boosts differences in activity between the two options reflecting object value or action value (*bottom*). Alternatively, and more effectively, the signal may enhance activities representing chosen object or chosen action selected by the winner-take-all (WTA) mechanism (*top right*), while leaving nonexisting activity unchanged (*top left*). The weight of dots and lines in the circuit model indicates level of neuronal activity. Dotted lines indicate inputs from unchanged neuronal activities. Crossed green connections are inhibitory.

neurons via optogenetic activation of local, presynaptic GABA neurons reduces reward consumption (613). At the postsynaptic level, optogenetic stimulation of dopamine D1 receptor expressing striatal neurons increases behavioral choices toward contralateral nose poke targets, whereas stimulation of D2 receptor expressing striatal neurons increases ipsilateral choices (or contralateral dispreferences) **(FIGURE 46*C*)** (576), suggesting an immediate, differential effect on reward value for the two actions.

Whereas these effects are straightforward, stimulating a couple synapses upstream of dopamine neurons induces surprisingly complex effects. Optogenetic activation of tegmental inputs to dopamine neurons projecting to nucleus accumbens elicits place preference, whereas stimulation of habenula inputs to dopamine neurons projecting to frontal cortex induces place dispreference (303). Whereas place preference signals reward, dispreference reflects either aversion or reduced reward. The dispreference might be due to monosynaptic excitation of aversive coding dopamine neurons, as suggested by FOS gene expression and excitatory currents (EPSCs) in dopamine neurons and by blunting of the dispreference with prefrontal D1 antagonists (303). However, dopamine neurons are not activated by aversive stimulus components (157, 160), FOS activation is slow and may derive from rebound activation following dopamine depression (158, 566), EPSCs do not necessarily induce action potentials required for dopamine release in target areas, and the optogenetic stimulation of presumed dopamine neurons might have included non-dopamine GABA neurons in used TH:Cre mice (304). Alternatively, dispreference might reflect disynaptic inhibition of dopamine neurons via the inhibitory rostromedial reticular nucleus (613). The monosynaptic habenula-dopamine projection is weak (625), and electrophysiology reports depression-activation sequence of VTA and nigral dopamine impulse activity following habenula stimulation (95, 250, 344, 566) that likely involves the inhibitory rostromedial reticular nucleus (226, 249). Furthermore, habenula glutamate receptor blockade increases striatal and prefrontal dopamine concentrations, probably reflecting blockade of the inhibitory habenula-dopamine projection (310). The prefrontal D1 antagonists likely blunt all prefrontal dopamine effects irrespective of excitation or inhibition. Thus the place dispreference with habenula stimulation unlikely reflects monosynaptic activation of aversive coding dopamine neurons and rather results from inhibiting dopamine neurons via the reticular nucleus. Indeed, a recent study reports inhibition of dopamine neurons and behavioral dispreference by electrical habenula stimulation. Similar place dispreference is elicited by activating midbrain GABA neurons that inhibit dopamine neurons (613) or by directly inhibiting dopamine neurons (244, 582). Thus the approach and dispreference elicited by differential input stimulation are likely the results of transsynaptically induced increased and reduced dopamine reward signals, respectively.

The immediate behavioral dopamine effects may be captured by a simplifying account that incorporates the essentials of immediate dopamine influences on behavioral choices into a generic competitive decision model **(FIGURE 47)**. To have an immediate effect, the dopamine signal

should reflect the prediction error at the time of the decision preceding the final reward. This error is the TD reward prediction error between the current prediction reflecting the chosen value minus the preceding reward prediction. The signal may influence neuronal activity for two kinds of decision variables. A dopamine-focusing effect (70, 368, 594) on predecisional object value or action value signals would enhance the value difference between the two options in a graded manner. The indiscriminate dopamine signal would affect all active synapses on neurons coding by definition object value and action value irrespective of the decision. Such dopamine influences on action value coding were assumed to explain the differential effects of optogenetic stimulation of D1 and D2 containing striatal neurons on behavioral choices (576). A more divisive dopamine influence would be achieved by affecting neurons that code the postdecisional variables of chosen object or chosen action before the overt behavioral choice (**FIGURE 47**, *right*). Activity in these neurons is differential due to selection by the WTA decision mechanism. The nonexisting activity from the unchosen option would not be enhanced by the dopamine signal (left). Thus the WTA mechanism would provide selectivity for the indiscriminate dopamine influence. Taken together, the basic comparator model of decision-making provides an architecture possibly underlying the immediate influence of the phasic dopamine signal on decision processes. This hypothesis is intentionally crude and provides only a general account, without addressing details of implementation by different types of dopamine innervated neurons in striatum, frontal cortex, and amygdala.

13. Formal neuronal decision models

The remarkable correspondence of neuronal signals to the key features of decision models encourages the development of biologically inspired neuronal models of decision-making. In many of such models, the economic decision variables of individual choice options are processed in separate pools of spiking neurons. The ramping activity is generated from transient inputs by recurrent synaptic excitation involving AMPA or NMDA receptors to induce self-sustained attractor states and integrate sensory or value information. The competition between choice options is mediated by GABA neurons exerting mutual, lateral, feedforward, or feedback inhibition between the neuronal pools for the choice options. The WTA mechanism combines the inhibition with a thresholding mechanism that leads to acceleration of ramping activity or to all-or-nothing selection between signals. The winning suprathreshold activity then propagates to pools of output neurons that mediate the behavioral action.

For neuronal decision models involving the cerebral cortex, key features are the discovery of explicit neuronal decision signals and the local synaptic connectivity. A generic model for perceptual discrimination of random dot motion direction in LIP neurons uses a difference signal derived from pools of specific direction-sensitive input neurons from middle temporal (MT) cortex (535). For example, larger activity in rightward compared with leftward motion coding MT neurons results in an LIP difference signal for rightward motion. The activity begins with appearance of the moving dots and accumulates over time with the continuing incoming noisy evidence about dot motion direction until it reaches one of the two decision thresholds. This model conforms to a diffusion model with continuous comparison between options and activity diverging towards one of several thresholds (55) and fits well the experimental data (535). Through its generality, such a model would also fit economic decision processes during which LIP neurons code the log likelihood ratio decision variable in a sequential probability ratio test (643), which constitutes an efficient decision mechanism (619).

A cortex model of two-stage somatosensory frequency discrimination uses two mutually inhibitory pools of 250 noisy spiking neurons that represent the two choice options (334). The model neurons show sustained activity that scales with the frequency of the first, transient vibratory stimulus until the comparison stimulus occurs. The subsequent activity conforms to an abstract decision signal that does not vary with individual stimulus frequencies. The sustained activity and its transition from mnemonic coding to decision signal resemble closely the activity of prefrontal and premotor cortex neurons of monkeys in this task (65, 212, 488, 489). The model achieves categorical decisions by discriminating between vibratory stimuli irrespective of their actual frequencies and thus supports the function of the experimentally observed neuronal signals in perceptual decisions.

More elaborate cortical neuronal decision models employ architectures comprising frontal and parietal cortex, basal ganglia, and superior colliculus **(FIGURE 48*A*)** (323, 622, 623). Transient inputs induce persistent activity with slow temporal integration via recurrent cortical NMDA and AMPA mediated excitation. Mutual lateral inhibition between pools of 240 irregularly spiking neurons mediates the competition between the stochastic choice options. By excitatory attractor dynamics and WTA competition throughout decision formation, the ramping activities in the neuronal pools representing the choice options become increasingly more separated in their race toward specific decision thresholds. The ramping activities reflect evidence accumulation or decision variables such as event likelihood ratio for perceptual decisions or object value, action value, and derivatives for economic choices. The cortical activity exceeding the competition threshold is detected by the superior colliculus via direct or double inhibitory influences through caudate nucleus and pars reticulata of substantia nigra and then propagated to the oculomotor system. The modeled neuronal activities replicate well the experimentally observed

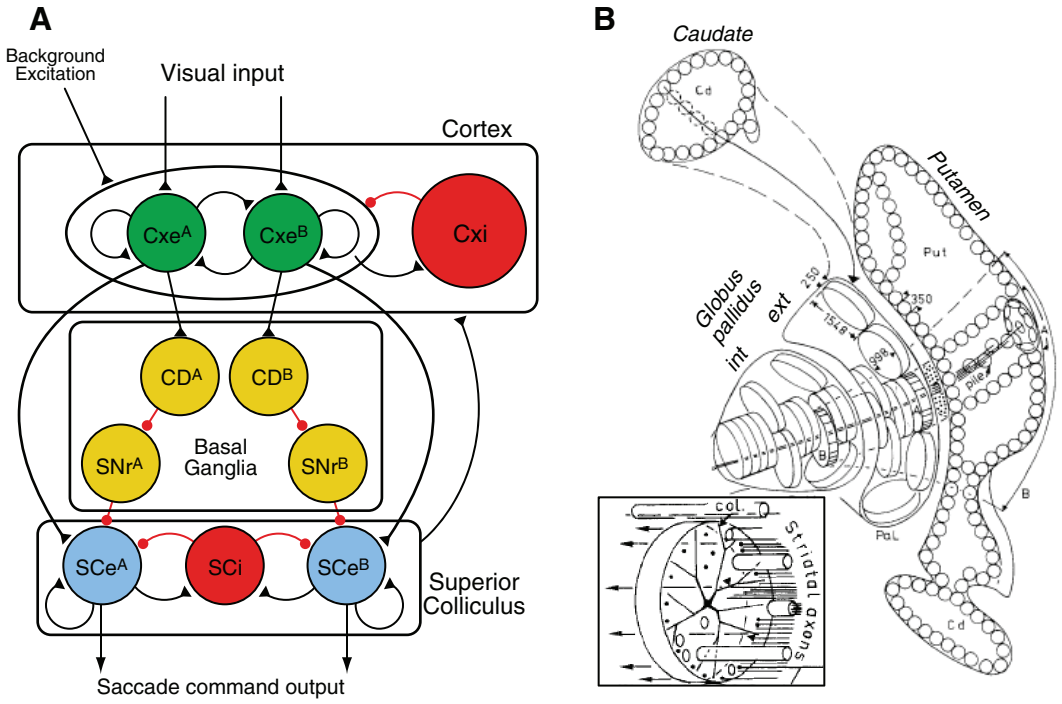

FIGURE 48. An example economic decision model and key anatomical foundations. *A:* architecture of a sensory or value decision model involving the cerebral cortex and basal ganglia. Recurrent excitations induce ramping activity in cortex (input to basal ganglia) and superior colliculus (output of basal ganglia), whereas lateral inhibition between neuronal pools representing the two choice options mediate competitive winner-take-all (WTA) selection of the better option at the input (cortex) and induce a corresponding ocular saccade at the output (superior colliculus). [From Wang (623), with permission from Elsevier.] *B:* anatomical convergence of neurons from striatum (caudate and putamen) onto dendritic disks of neurons in globus pallidus (internal and external segments) in monkey. The dendritic disks represent an abstraction of the wide dendritic arborizations that are oriented orthogonally to axons traversing the globus pallidus from the striatum. *Inset* shows several axons from striatal neurons traversing and contacting the pallidal dendritic disks. These parallel striatal axons induce substantial anatomical striatal-pallidal convergence by contacting the dendrites in the disks. [From Percheron et al. (430). Copyright 1984 John Wiley and Sons.]

ramping in frontal and parietal neurons described above. Dopamine-mediated three-factor Hebbian reinforcement learning may set the decision threshold in caudate nucleus or cortex (554). Thus cortical WTA determines the ramping, superior colliculus detects threshold crossing, and dopamine neurons set the threshold.

For neuronal decision models involving the basal ganglia, key features are the well-organized corticostriatal projections, internal connections, and parallel loops with cortex (7, 141, 164, 196, 197, 252); the synaptic convergence through the component structures **(FIGURE 48*B*)** (416, 430); the separate striatal outputs with sequential inhibitory neurons (93, 127); and the dopamine-mediated plasticity of corticostriatal connections (424, 517, 540). The basal ganglia may be involved in two distinguishable aspects of decision-making, namely, the direct selection of options and the updating of option values through reinforcement learning (57).

Option selection in the basal ganglia employs the dopamine focusing effect (70, 368, 594) and anatomical convergence in striatum and globus pallidus (416, 430) **(FIGURE 47)**. The models employ physiological activities and known input-output relationships of basal ganglia nuclei to demonstrate the feasibility of movement selection (72). By implementing the efficient sequential probability ratio test, the scaled race model shows that the subthalamic nucleus modulates the decision process proportionally to the conflict between alternatives (57). It outperforms unscaled race models. Particularly good fits are obtained with a diffusion model of movement selection (449). The basal ganglia decision models are supported by experimental data not used for their construction and also elucidate economic decision mechanisms, including the differential effects of optogenetic stimulation of dopamine D1 and D2 receptor expressing striatal neurons **(FIGURE 46C)** (576). The opposing functions of the direct and indirect striatal output pathways are modeled by a race between movement and countermanding signals that reflect the relative timing of the two signals as they race towards a threshold (511). The signals fit experimentally observed activities in rat substantia nigra neurons. These studies provide key support for important basal ganglia contributions to motor selection and economic decisions.

Updating of object value, action value, and their derivatives by the basal ganglia employs dopamine prediction error signals (517) **(FIGURE 45)**. Data analyses routinely employ the modeled subjective values of choice options as regressors for neuronal value coding and action value updating in the striatum (245, 267, 275, 306, 500, 530). Reinforcement models distinguishing between direct and indirect striatal pathways are based on in vitro work (424, 540) and assume that dopamine prediction error signals have differential plasticity effects on D1 versus D2 receptor expressing striatal neurons (72) and induce the learning of respective choice preferences and dispreferences (169). These results from formal models closely reflecting physiological data confirm the capacity of dopamine reinforcement signals for learning and updating of economic decision variables.

E. Reward and Free Will

Current notions about free will range from extreme determinism, in which every event of every individual at every moment is predetermined in advance by the mechanics of the world, to the capricious, unrestrained free will that puts intention and responsibility at each individuals' complete disposition and initiative. The truth lies probably somewhere in between. There are likely neuronal mechanisms involving stochasticity that are constrained by external influences and generate choice options within a limited range. Deliberate actions might originate from these neuronal mechanisms and operate within these constraints. Constraints are provided by reward value and all factors influencing it, including effort cost, delay, risk, and references, that affect brain processes underlying decision-making. Without trying to provide a coherent view, I will sketch a few thoughts along these lines.

1. Origin of free will (the impossible question)

Assuming that free will exists at all, we simply do not know how it may originate, and we have only faint ideas how brain processes might generate it. We argue even whether free will originates in the brain. For Kant, free will lies above all activity, irrespective of physical, biological, psychological, and social constraints. For him, only God has free will, as s/he has created everything. But admitting that we do not know anything is the easy answer. We can try to reduce this impossible question to tractable issues by trying to understand the mechanisms determining free will.

Free will has several necessary components. First, free will depends on the ability to make choices, to do what we want to do (219). Second, free will implies a voluntary action that is self-directed and arises on self-command. Free will does not apply to vegetative reactions that I cannot control, like heartbeat, intestinal contractions, or hormone release, nor to probably most Pavlovian reactions and many habits. Third, the word *will* indicates a goal that we want to achieve. Thus free will would be instrumental in generating voluntary, goal-directed behavior. Fourth, free will involves conscious awareness about the goal directedness. We think we have free will because we know explicitly that we are working towards something we want. And we know that we want this something, however diffuse this may be in exploratory behavior. We feel the freedom to choose when to act and which of several options to select. This feeling is subjective, private, and unobservable by others. It is difficult to measure objectively, and it may not even be real but an illusion (634), nobody knows for sure.

The fact that free will has emerged in evolution suggests a beneficial function for the competitive survival and reproduction of individuals in their function as gene carriers. As much as the idea of a conscious illusion of free will may be disappointing, evolutionary biology teaches us that a structure or function may enhance the chance for survival without necessarily evolving to perfection. Thus it may not matter whether conscious free will is an illusion or real, as long as it is helpful for keeping the genes in the pool. Thus free will is a psychological tool for gene propagation.

What we do know is that we need rewards for survival (essential substances contained in food and drinks) and reproduction (sexual rewards). It would be advantageous to seek these hidden rewards actively rather than waiting for them to appear out of the blue. That is why we can move. Intentions and free will would be a great help to seek and explore rewards actively and deliberately, rather than running after them using deterministic programs. Without the true or false belief of free will, we may have only limited initiative to find hidden rewards. The main advantage of free will is the subjective experience of free will, which makes the search for hidden rewards more deliberate and focused, and thus saves time and is more efficient in many situations. Dennett (128) argues that consciously sensing free will is a crucial characteristic of free will. The evolutionary benefits driving the appearance of free will would be the boost in initiative, resulting from the conscious belief that we can deliberately decide our own behavior. This belief is also the basis for moral responsibility and thus helps social coherence. And adding theory of mind would make me understand others' free will and voluntary behavior and further facilitate social processes.

One view on conscious free will assumes that it is generated from scratch and makes us completely free to do what we want. There are only two possibilities to generate this sort of free will. First, brain activity generates the conscious awareness as necessary hallmark of free will. This brain activity necessarily precedes the conscious awareness and thus cannot be directed by free will. In this case, free will would not be free but an illusion of freedom that follows the uncontrolled generation of free will

by the brain. Alternatively, it is not brain activity but something nonmaterial that leads to conscious awareness of free will, and then brain activity carries out what the nonmaterial event has directed it to do and signals free will. Both scenarios seem unresolvable and therefore depressing and ultimately unconstructive. However, the problem may be overcome by taking a step back to consider the neuronal mechanisms by which free will might arise in more realistic situations in which it is seriously constrained by a number of factors. Even in this restricted form, free will would still provide an evolutionary beneficial, conscious control over our actions.

Everyday neurophysiological experiments tell us that many, maybe most, neurons in the brain are spontaneously active without any observable stimuli or actions. Thus brains generate their own activity. We also know that we have many mental experiences that seem to arise spontaneously out of nowhere, even in fully awake and nonpathological states, like thoughts, imagination, and old memories. How could I write this text if I could not sit back (with the proverbial cup of tea) and listen to the ideas that are popping up in my head (most of them rubbish, but occasionally a useful one), and then find the words and put them into grammatically correct order? Neuronal activity in cortex and striatum ramps up over several seconds before self-initiated movements but not before externally instructed actions (299, 311, 337, 380, 397, 491, 493, 526, 528). The key to explaining such brain activity may be the tendency to stochastic activity in many neurons and networks (129, 167, 180, 195). Once initiated by random molecular fluctuations (94, 287, 561, 567), the noise may result at some point in organized activity (168, 200, 297, 330, 465, 564, 611) and influence or settle in attractor states (63, 125, 510) that result in mental events. The hardware of the individual's brain and the individual's experience would constrain the range of attractor states producing mental events. A person who has never done or watched or heard about underwater diving may never experience a spontaneous imagination of the color of corals, nor the free will to go diving to see this. Thus the stochastic brain activity would arise spontaneously, relate to past experiences, and not be initiated from scratch by free will (nor do we need to assume nonmaterial origins).

The spontaneously occurring attractor states arising from initially stochastic neuronal activity would not need to be conscious. Several such elementary unconscious attractor states may develop at the same time, each of them representing a different future option for intention. The possibility of developing attractor states from stochastic activity would not be infinite but depend on brain activity restricted by hardware, current environment, and memory from earlier experience. Thus the attractor states would be restricted to viable options within boundaries. Impulses that never come up cannot be selected. Attractor states related to the intention of exploring the color of corals may only occur if my brain can process color and if I have ever heard about colorful corals. Then a selection mechanism would be set in motion in which viable options emerge with a certain degree of variation within bounds defined by hardware and personal experience. The process may resemble the selection of a reasonable option from a rotating initiator of options. There would be no deliberate, free initiative involved in this selection, as not only the attractor states but also the selection process and its boundaries would be unconsciously mechanical. Only the result of the selection would pop up into consciousness and be interpreted as free will. This conscious free will is not an illusion but the result of unconscious processing. From this point on, it would be possible to decide consciously whether to follow the selected impulse for action or to resist, to select consciously between the emerging mental images and intentions (e.g., separating rubbish from nonrubbish in writing), or to listen further to solutions from those popping up. Thus the unconscious processes produce a scratchpad that pops into consciousness and from which conscious free will can choose freely or veto an intention. This might be what is usually associated with the term of free will and the individual's responsibility for their own intentional actions.

Of course, there may be completely different, currently unknown processes besides stochasticity that may generate brain states underlying free will. The idea would require the discovery of new phenomena in physics (429). However, some of the described steps in the emergence of free will may still hold, in particular the dilemma in the initiation of free will between the brain's hardware and the mind.

2. Constraints on free will

Although free will is associated with being able to make choices (219), I can only choose between the options that are available. We are just not free to choose between anything imaginable, but our options are restricted by the physical state of the world (we cannot fly to Mars), our body's hardware (we cannot fly like birds), and our personal experiences and education (most language scholars do not do partial differential equations). Even among the available options, our choices are influenced by factors not considered as economic value such as emotions driven by external events, social pressure and conventions, altruism, moral rules, and irrational beliefs such as nationalism, chauvinism, prejudices, and superstitions. These external and internal constraints reduce free will in a graded manner, and up to its complete loss when constraints become too serious. Of course, survival is the strongest and most natural constraint on free will. Only within these bounds is free will free.

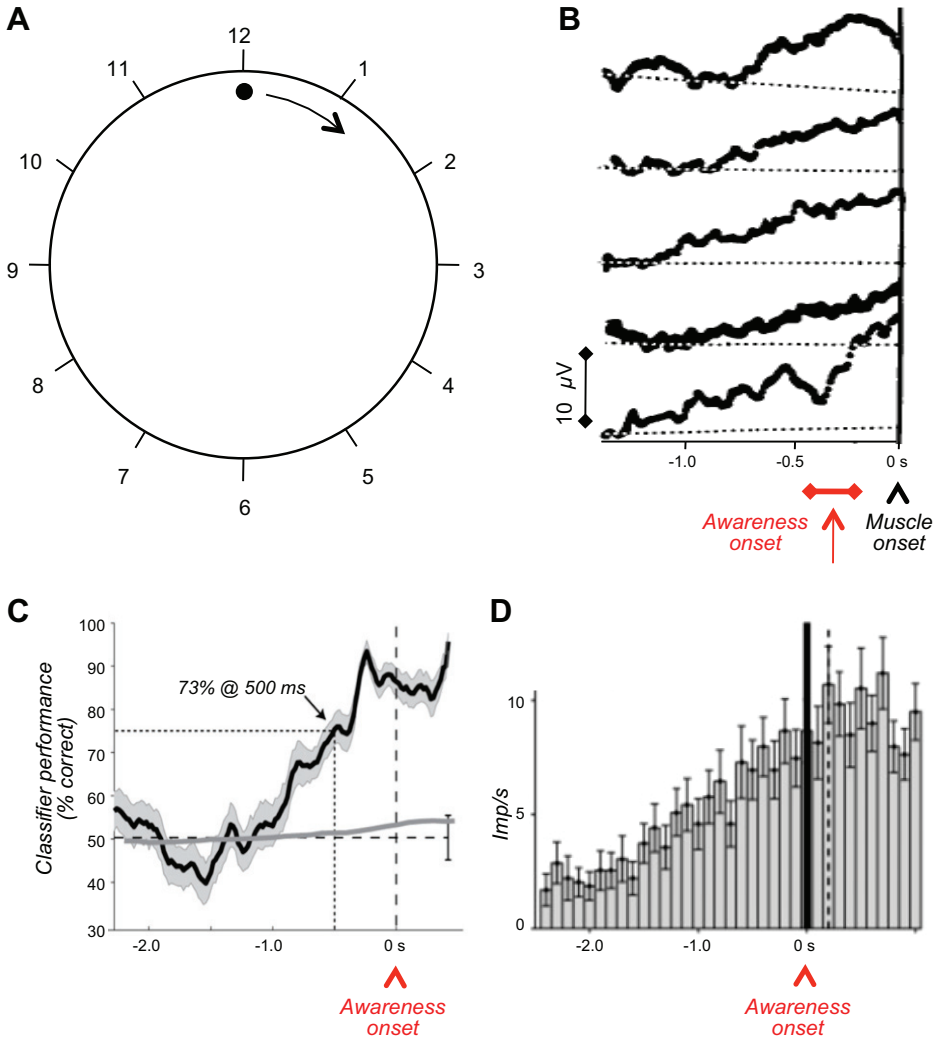

FIGURE 49. Unconscious onset of conscious awareness to act. *A:* design of Libet's classic experiment. A dot moves clockwise around a circle. Subjects remember the dot position at which they became consciously aware of the urge to do a self-initiated finger or wrist movement and report the dot position after being prompted. *B:* electroencephalographic readiness potential recorded at the vertex (top of skull) of one human participant (average of 40 trials). Onset of aware urge to move is indicated in red (bar shows range from eight averages of 40 trials each). Muscle onset denotes onset of electromyographic activity in involved forearm muscle. [From Libet et al. (316), by permission of Oxford University Press.] *C:* detection of time and occurrence of deviation from baseline activity in 37 single and multiple neurons before awareness to act, as determined by a support vector machine classifier. The neurons or multineuron clusters are located in human supplementary motor area (n = 22), anterior cingulate cortex (n = 8), and medial temporal lobe (n = 7). *D:* ramping activity preceding the conscious awareness to act in activity averaged from 59 neurons in human supplementary motor area. [*C* and *D* from Fried et al. (172), with permission from Elsevier.]

Free will can be constrained and focused. A good example is intention in action (529). I choose deliberately a course of action that allows me to form short-lived intentions on the fly while I am moving. I choose to do a walk through town and find a shop window that attracts my intention and makes me buy a pair of boots for the winter. My free will is partly restricted by the decision to take the walk, and the shoe purchase reflects that constraint. My purchase may simply be triggered by the view of the shoes, their price, and their relationship to my purchasing habits and personal preferences. The intention to enter the shop comes instantaneously, almost as a reaction to the sensory input. Very little free will is involved in the final purchasing action after I have initiated the walk.

In a similar situation of very restricted free will, humans indicate the moment at which they consciously perceive the awareness to initiate a simple finger movement **(FIGURE 49*A*)** (316). Indeed, the participants become aware of the urge to move only several hundred milliseconds after the onset of electroencephalographic brain activity for the movement (readiness potential, **FIGURE 49*B***). Sensory and motor confounds are excluded. The only conscious component consists of the possibility to veto the arising urge to move before the actual movement starts. Action-specific preparatory increases of BOLD signals in frontopolar and parieto-cingulate cortex precede the conscious awareness to move by 7–10 s (555). The activity of single neurons in humans preceding self-initiated movements predicts the awareness to move by 500 ms with 70–90% precision **(FIGURE 49*C*)**. These potentials may originate in nonintentional, spontaneous fluctuations reflecting a state of neuronal propensity toward action initiation, true to the meaning of the word "readiness potential" (515). At the neuronal level, such spontaneous fluctuations might occur below action potential threshold but are not conspicuous when recording action potentials during self-initiated movements in the supplementary motor area and associated cortical and subcortical structures in monkeys not expressing awareness to move (299, 311, 337, 380, 397, 491, 493, 526, 528) **(FIGURE 37*C*)** and in the supplementary motor area and anterior cingulate cortex in humans 1–2 s before the awareness to move **(FIGURE 49*D*)** (172). Thus it appears

as if the brain's hardware initiated the movement without the participant's own initiative, suggesting that conscious free will does not exist in these experiments. It is tempting to deny the general existence of free will on the basis of these results. However, the voluntary submission to the experiment may put so many constraints on the liberty of the participant that indeed there is no free will left and the brain is able to initiate the movement without conscious free will, just like the shoe buying example. Thus the experiments employ the role of constraints on free will in an extreme manner and test intention in action rather than true free will. In doing so they may reveal the existence of the elementary process outlined above by which stochastic brain activity settles spontaneously into an attractor state without conscious awareness and only afterwards leads to a conscious mental state. The consciously aware urge to move is then simply a retrograde interpretation of an unconsciously initiated action following the conscious selection to undergo the experiment.

3. Rewards exert constraints on free will

Rewards are necessary for survival. Without rewards we would die of thirst within days and of hunger within weeks, depending on our adipose reserves. With that function, rewards influence and thus constrain behavior and restrict free will in several ways. The passive experience of rewards attracts behavioral reactions away from other objects and focuses behavior onto the available rewards. Entering active decisions between rewards is not very free either because we need rewards at some point for survival. Once we are able to decide, we choose the best option, called utility maximization in economics, to ensure the highest chance for survival and gene propagation. Choices in such restricted situations may often reflect intentions in action, similar to the Libet experiments on movements, and involve serious constraints on free will. The choices are easy to do when the options are limited and have clearly different values, in which case there is little scope for free will, but the choices are more difficult when more, and more similar, options remove some constraints on free will. Habits for acquiring rewards impose particularly strong constraints on free will, and addictions to natural and artificial rewards eliminate free will even more. The initial administration of an addictive substance, like nicotine, is done with free will, often constrained by peer pressure, but following the habit once serious addiction has set in is almost deterministic.

All additional factors affecting reward value add to the constraints on free will. Motivational states like hunger and thirst make rewards more valuable and prioritize our behavior, as easily seen before lunch and dinner. Rewarding contexts make us long for rewards. Who would work during an office party when colleagues drink wine and tell interesting stories? Work required to obtain rewards seriously focuses our actions. Many animals spend most of their day searching for food. Temporal discounting of future rewards hinders our planning and favors myopic actions. Reference-dependent valuation makes us slaves of our environment. Nobody wants to lose what they have achieved, and keeping up with the Joneses is hard work, both of which require good focus and constitute constraints.

Risk exerts huge constrains on our behavior. Risk avoidance makes us shy away from risky situations even if they might be beneficial in the long run. The inability to completely eliminate risk induces anxiety, prejudice, and superstition which further direct behavior in serious ways, up to generating wars without reason. Risk management and the desire for risk reduction are prevalent in all cultures. Many activities of daily life are aimed at reducing risk, from paying car and health insurance to ritual sacrifices. The first reaction of the Minoan people to the devastating Santorini volcano eruption was human sacrifices to appease the angry gods. Risk reduction becomes a part of the culture, influences the whole life history of individuals, and thus takes some free will away.

The constraints exerted by rewards on free will extend also to the learning about rewards. Pavlovian reward predictions arise automatically following repeated exposure without the subject's own doing, which constrains free will substantially. Operant conditioning involves own action and allows goal-directed behavior, which constrains free will a bit less than Pavlovian predictions. Conditioning and higher forms of learning are evolutionary beneficial, as they increase reward acquisition for survival and gene propagation, but in doing so they constrain free will considerably.

Genetic dispositions, education, and long-term reward experience are instrumental for establishing personal reward preferences that influence the whole life of individuals. Different individuals prefer different rewards and choose their profession accordingly (among many other factors). They become mechanics because they appreciate precision, bankers for the money, musicians for the beautiful sounds, doctors because of altruism, and scientists because they value curiosity and knowledge highly. The impact of these preferences accumulates over the whole life span and shapes the personality. All of these influences constrain free will. Even seemingly free changes in personal reward preferences due to physiological factors and personal experience do not much enhance free will.

Punishers constitute the second major class of motivators of behavior besides rewards. Punishers derive from external sources over which we have little control, and they need to be avoided to escape their damaging impact. Thus avoidance is a reaction to events that occurs without one's own doing. There may be different options for escape, and thus limited scope for free will, but overall avoidance involves little free will, allows little deliberation, and produces primarily reactive rather than proactive behavior. The choices

between punishers seem to allow some degree of liberty that is intrinsically low when being forced into the choice. According to the *New York Times* of April 23, 2010, prisoners sentenced to capital punishment in Utah may choose between hanging and a firing squad. "I would like the firing squad, please" reportedly said Ronnie Lee Gardner. Overall, some liberty exists when being able to proactively search for best solutions for efficient avoidance. We can think of known dangers and generate preventive measures, but it is hard to imagine totally unknown dangers and be creative in planning their avoidance. Thus punishers may exert even more constraints on free will than rewards.

4. Neuronal reward processing constrains free will

Electrical and optogenetic stimulation of dopamine neurons are very efficient for eliciting immediate behavioral reactions and behavioral learning **(FIGURE 19, *A–D*)** (2, 103, 155, 562, 605, 641). The strength of dopamine stimulation affects choices, reaction times, and reward acquisition in a graded manner. The animals are simply driven towards goals associated with the dopamine activation, both during the stimulation (immediate effect) and in the next test sessions (reinforcement learning). Thus, in focusing individuals on rewards at the expense of other pursuits, dopamine stimulation takes parts of free will away from the individual's behavior.

Dopamine stimulations are not experimental artifacts but mimic the natural phasic dopamine responses to reward prediction errors. The dopamine responses are likely to have similar behavioral effects as the stimulation. Even though stimulation parameters differ somewhat from the natural responses, the important feature is the brief, phasic dopamine activation, whereas slow, tonic dopamine stimulation is ineffective (e.g., for place preference learning; Ref. 605). The dopamine effects likely involve synaptic plasticity and focusing in striatum and frontal cortex (70, 368, 424, 540, 594). Indeed, optogenetic stimulation of striatal neurons postsynaptic to dopamine neurons induces differential approach and avoidance learning and behavioral bias depending on the dopamine receptor subtype the stimulated neurons carry **(FIGURES 19*F* AND 46*C*)** (293, 576). Thus the combined evidence from dopamine stimulation and dopamine reward responses indicates that eliciting a strong reward signal in dopamine neurons directs the organism towards reward and thus constrains its free will. This is the mechanism through which primary (unpredicted) rewards and (Pavlovian) reward predictors influence the behavior and constrain free will.

A similar argument may hold for neuronal risk processing. Dopamine and orbitofrontal reward neurons code risk separately from value **(FIGURE 31*C*)** (161, 162, 391, 392). Furthermore, neuronal risk signals, and the influence of risk on neuronal value signals, vary with individual risk attitudes (301). If these risk signals could affect risk components in behavior analogous to value signals, they would provide mechanistic explanations for the constraining influence of risk on free will. To demonstrate such an effect, one would need to demonstrate that selective stimulation of risk neurons, such as those found in orbitofrontal cortex, affects risk attitudes during choices.

The strength of the dopamine response seems to convey the influence of rewards on behavior. Rewards with stronger effects on dopamine neurons are likely to have more impact on learning and choices. Thus the propensity of individual rewards to activate dopamine neurons would determine the influence of reward on behavioral choices. This function may hold also for other reward centers in the brain, although their less compact organization may not be conducive to such dramatic stimulation effects. However, it is unlikely that a response of dopamine neurons or other reward neurons to an automatically conditioned, reward-predicting stimulus induces approach behavior entirely without the subject's own doing. There are other brain mechanisms that would limit the automaticity of such effects, but any neuronal reward signal is nevertheless likely to have a biasing effect towards rewarded stimuli and actions. The neuronal responsiveness to different rewards is likely to vary between individuals. Interindividual differences in reward processing may affect daily preferences but also determine long-term behavior, including professional choices and other important decisions in life. Thus the activity of reward neurons shapes behavior, constrains voluntary decisions, and thus restricts free will.

ACKNOWLEDGMENTS

I thank Anthony Dickinson for 20 years of discussion and collaboration on animal learning theory, Peter Bossaerts and Christopher Harris for 10 years of discussion and collaboration on experimental economics, and Peter Bossaerts, Anthony Dickinson, Fabian Grabenhorst, Armin Lak, Johannes Schultz, William R. Stauffer and two anonymous referees for comments. I am indebted to Colin F. Camerer, David M. Grether, John O. Ledyard, Charles R. Plott, and Antonio Rangel for discussing experimental economics at the Division of Humanities and Social Sciences, California Institute of Technology, Pasadena.

Abstract

Childhood adversity is strongly linked to negative mental health outcomes, including depression and anxiety. Leveraging cognitive neuroscience to identify mechanisms that contribute to resilience in children with a history of maltreatment may provide viable intervention targets for the treatment or prevention of psychopathology. We present a conceptual model of a potential neurobiological mechanism of resilience to depression and anxiety following childhood adversity. Specifically, we argue that neural circuits underlying the cognitive control of emotion may promote resilience, wherein a child's ability to recruit the frontoparietal control network to modulate amygdala reactivity to negative emotional cues—such as during cognitive reappraisal— buffers risk for internalizing symptoms following exposure to adversity. We provide preliminary support for this model of resilience in a longitudinal sample of 151 participants aged 8-17 years with (n=79) and without (n=72) a history of childhood maltreatment who completed a cognitive reappraisal task while undergoing fMRI. Among maltreated youth, those who were better able to recruit prefrontal control regions and modulate amygdala reactivity during reappraisal exhibited lower risk for depression over time. By contrast, no association was observed between neural functioning during reappraisal and depression among youth without a history of maltreatment. These preliminary findings support the hypothesis that children who are better able to regulate emotion through recruitment of the frontoparietal network exhibit greater resilience to depression following childhood maltreatment. Interventions targeting cognitive reappraisal and other cognitive emotion regulation strategies may have potential for reducing vulnerability to depression among children exposed to adversity.

Childhood adversity, which robustly predicts psychopathology (1–3), refers to negative experiences that deviate from the expectable environment, requiring meaningful adaptation by an average child (4). These experiences can reflect either *threat*, defined as relating to harmful experiences, or *deprivation*, the absence of expected environmental inputs, such as caregiver support and cognitive stimulation (5–7). The current paper focuses on childhood adversity in the form of threat, specifically maltreatment (e.g., physical or sexual abuse), as it has particularly strong ties to depression and anxiety (3, 8–10).

Although childhood adversity is a powerful predictor of psychopathology, this relationship is not deterministic; many children who have encountered severe forms of adversity demonstrate resilience and do not go on to develop mental health problems (11–15). Resilience involves processes that buffer children from risk for these negative consequences (16). Identifying mechanisms of resilience may reveal targets for preventative interventions designed to protect children following adversity (4). Considerable work examines factors that promote resilience (15, 16), but few studies examine neurobiological mechanisms conferring resilience among children exposed to threat-related adversity. Here, we advance a neurobiological model of resilience, focusing on neural circuits underlying the cognitive control of emotion. Specifically, we posit that a child's ability to recruit the frontoparietal control network to modulate amygdala reactivity to negative emotional cues—such as during cognitive reappraisal and other effortful forms of emotion regulation— buffers risk for internalizing symptoms following exposure to adversity. We provide preliminary data testing this proposed framework using neuroimaging data of cognitive reappraisal in a longitudinal sample of children and adolescents exposed to maltreatment.

Defining Resilience

Developmental and clinical psychologists have long been interested in resilience, and various definitions have been proposed. Some have conceived of resilience as a fixed trait or set of traits that are immutable (17–19) and may be present within an individual whether or not they have experienced adversity (20). Instead, we utilize the definition that resilience reflects an absence of negative outcomes despite exposure to adversity (15, 16, 21). To study this form of resilience from an empirical perspective, one must identify specific factors or developmental processes that moderate the association between adversity and negative outcomes, such that the adversity-negative outcome relationship is weaker among those who have higher levels of the resilience factor.

Resiliency factors can occur at multiple interacting levels of the bioecological milieu (22–24), from entire cultures (25) to neighborhoods (26) to families (27) to children's temperaments (28) all the way down to individual genes (29). In addition, the factors that lead to resilience may depend on the nature of the adversity experienced and the social and cultural context to which an individual must adapt (24). Developmental cognitive neuroscience may generate unique insights into resiliency factors. Work in this area can be leveraged to identify resilience mechanisms at the level of specific cognitive-affective processes and their underlying neural networks that confer protection against psychopathology following experiences of adversity. Moreover, a rich history in this area informs research performed at the therapeutic level (30). Identifying specific neurobiological, cognitive, and affective mechanisms of resilience that are modifiable is critically important for informing models of risk and resilience, as well as identifying viable targets for intervention to treat or prevent psychopathology (4).

Here, we advance the possibility that the effective engagement of cognitive control networks in service of modulating negative emotions may be a neurobiological mechanism of resilience to depression and anxiety following childhood adversity. Neural circuits underlying the cognitive control of emotion, including the frontoparietal control network, have been most studied in relation to the emotion regulation strategy of cognitive reappraisal.

Cognitive Reappraisal

Cognitive reappraisal involves thinking about a stimulus in a way that changes the meaning to modify one's emotional response (e.g., to reduce negative or enhance positive emotion) (31–36). Cognitive reappraisal has been shown to modulate emotional responses in experimental settings (31, 32, 37–40), real-world settings (38, 41), and clinical intervention studies, where training to enhance reappraisal is associated with reductions in symptoms of depression and anxiety in children and adults (42–44).

Functional magnetic resonance imaging (fMRI) studies reveal a network of brain regions recruited during cognitive reappraisal that modulate amygdala activation (45). These studies typically use specific reappraisal strategies, such as psychological distancing or reinterpretation, as tactics for reducing emotional responses to negative stimuli (e.g., images of a car crash) (31, 34, 35, 46–49). Meta-analysis shows that during cognitive reappraisal compared to passive viewing of emotional stimuli, regulatory regions of the frontoparietal network are engaged and modulate amygdala activity (50). The frontoparietal regions recruited during cognitive reappraisal are broadly involved in cognitive control (51, 52) and include multiple prefrontal regions in both dorsal and ventral areas, the dorsal anterior cingulate, as well as posterior association cortex encompassing inferior parietal sulcus (31, 34, 50, 53–57). Recruitment of the

frontoparietal network during reappraisal may serve to select and maintain reappraisal-related features and goals while engaging in and monitoring progress of the construction of a new appraisal (45, 56).

Studies examining reappraisal in youth have shown that children as young as six years old can successfully employ this technique (57). Moreover, the extent of reappraisal success appears to improve linearly with age (36, 57–59) in association with increasing recruitment of prefrontal regions and diminishing activation in the amygdala, as well as greater inverse coupling between prefrontal regions and the amygdala (57). It should be noted, however, that some studies show behavioral indices of reappraisal success appear similar across development (60, 61), which could be explained by the type of reappraisal tactic being used (e.g., reinterpretation vs. distancing), as reinterpretation requires more complex, higher-order thinking.

Both adults and youth express patterns of frontoparietal recruitment during reappraisal in ways that modulate amygdala activation (36, 57, 59, 62–64). Given the amygdala's role in the processing of salient events (65–67), levels of amygdala modulation may reflect successful regulation of affective responding, although the specific patterns of connectivity that underlie this modulation remain a source of debate. Because lateral prefrontal regions have sparse direct projections to the amygdala, some studies suggest that activation in these regions modulates amygdala function via projections through the more densely-connected medial prefrontal cortex (53, 57, 68–72). Alternatively, lateral prefrontal regions may modulate amygdala activity via projections through lateral temporal cortex regions involved in semantic representation (34, 39, 50, 64). In either case, stronger inverse coupling between the prefrontal cortex and the amygdala is believed to produce greater reductions in negative emotion during reappraisal (53, 55). Below, we argue that the ability to successfully modulate the amygdala by recruiting this cognitive

control circuitry in the service of reappraisal is a key neurobiological mechanism of resilience to depression and anxiety following experiences of adversity.

Cognitive Reappraisal Neural Circuitry in Depression and Anxiety

Behaviorally, children and adults with depression and anxiety report similar reductions in negative emotion following reappraisal as those without psychopathology (31, 48, 73–77). However, those with depression and anxiety appear to use less efficient reappraisal strategies (73, 74). Disruptions in neural activation of frontoparietal and limbic regions involved in cognitive reappraisal have also been associated with depression and anxiety. However, findings vary across age and diagnosis. Some studies find affected relative to unaffected individuals to show greater recruitment of frontoparietal regions and heightened amygdala activity during cognitive reappraisal (48, 69, 73, 76), whereas others find affected individuals to show reduced recruitment across prefrontal regions (77, 78) or no amygdala differences (31, 75, 78). Taken together, data suggest that affected individuals manifest some form of disrupted prefrontal capacity to modulate the amygdala, which may reflect less efficient recruitment of regions supporting reappraisal processes.

Cognitive Control Circuitry as a Mechanism of Resilience following Childhood Adversity

The ability to effectively recruit frontoparietal circuitry in support of effortful emotion regulation strategies, such as cognitive reappraisal, could be a critical compensatory mechanism that may help to buffer against the heightened emotional and neurobiological reactivity that has been commonly observed following maltreatment and other forms of childhood adversity. Prior work consistently demonstrates that children exposed to adversity, particularly experiences of

threat, exhibit elevated emotional responses to negative stimuli assessed at multiple levels of analysis, including subjective report (79–82), autonomic nervous system response (83, 84), and amygdala reactivity (49, 85–89), the latter of which has also been confirmed in meta-analysis (90). Heightened emotional reactivity is a well-established risk factor for the emergence of depression and anxiety in youth (80, 81, 91–96). The ability to recruit frontoparietal circuitry to modulate amygdala reactivity may buffer children from internalizing problems that arise following these adversity-related increases in emotional reactivity. Indeed, among children exposed to adversity, preliminary evidence links greater structural and functional integrity within emotion regulatory circuits—encompassing connections between multiple regions of the medial prefrontal cortex and the amygdala—to resilience, in the form of lower risk for negative mental and physical health outcomes (97–100). These studies provide preliminary support for the notion that the ability to recruit prefrontal circuitry to modulate amygdala responses may be a neurobiological mechanism underlying adaptation to childhood adversity that dampens emotional and neurobiological hyper-reactivity to salient environmental stimuli, ultimately contributing to lower risk for psychopathology.

Effective cognitive reappraisal capacity may also be particularly important for children who have experienced adversity due to the strong continuity between exposure to adversity and subsequent exposure to stressful life events. Experiences of childhood adversity are highly co-occurring, such that children who experience one form of adversity (e.g., sexual abuse) typically experience several others (e.g., neglect and domestic violence) (1, 3). In addition, children exposed to adversity experience higher levels of stressful life events and chronic stress across academic, peer, and family domains (98, 101). Exposure to stressful life events and chronic stressors are well-established risk factors for depression and anxiety (102–105), and the link

between stressful life events and internalizing psychopathology is stronger among those who have experienced childhood adversity (101, 106–109). The ability to effectively utilize cognitive reappraisal may protect children from the negative mental health consequences of ongoing exposure to stressors, as has been shown in adults (110). Indeed, animal models of stress in non-human primate research support the notion that enhanced recruitment of regulatory circuits may promote resilience following early life stress (e.g., maternal separation; 111). For children who have experienced maltreatment, the capacity to flexibly deploy cognitive reappraisal and underlying control circuitry may be all the more important, considering the high likelihood that these children live in chronically stressful environments that frequently elicit negative emotions. However, no study to date has explicitly tested whether children's ability to explicitly engage effortful strategies and recruit prefrontal circuitry to modulate amygdala responses to negative emotional cues moderates risk for depression and anxiety following adversity.

Evaluating a Neurobiological Mechanism of Resilience

Using preliminary data from our group, we completed a set of exploratory analyses to provide an empirical test of our proposed mechanism of resilience. Specifically, we assessed whether the ability to modulate amygdala reactivity using cognitive reappraisal is a potential neurobiological mechanism of resilience to depression and anxiety among children exposed to maltreatment, a form of adversity that has particularly strong associations with internalizing psychopathology. If the proposed neurobiological mechanism of resilience is valid, we should expect that the association between child maltreatment and depression and anxiety symptoms will be lower among children and adolescents who exhibit: 1) greater modulation of amygdala responses to negative stimuli using cognitive reappraisal; 2) greater recruitment of prefrontal

regions known to be engaged during successful cognitive reappraisal; and 3) a greater tendency to use reappraisal strategies in their daily lives.

We examined these hypotheses in a longitudinal sample of 151 participants aged 8-17 with (n=79) and without (n=72) history of childhood maltreatment (e.g., physical or sexual abuse) who completed an emotion regulation task while undergoing fMRI. This task assessed neural activation during passive viewing and effortful attempts to regulate emotional responses to negative stimuli using cognitive reappraisal (Figure 1). Participants also reported on their tendency to engage in reappraisal in their daily lives. Symptoms of depression and anxiety were assessed at the time of the initial neuroimaging assessment and at a follow up assessment approximately two years later. See Table 1 for participant characteristics. All analyses were completed controlling for sex, age, race/ethnicity, and socioeconomic status (the income-to-needs ratio). We found no evidence for these patterns of resilience in relation to symptoms of anxiety. Below, we report the pattern of results for depression symptoms. For more details on participants, inclusion and exclusion criteria of the study, task design, measures, and analytical approach, see *Supplemental Materials.*

** TABLE 1 **

** FIGURE 1 **

Preliminary Evidence

Across the entire sample, the use of cognitive reappraisal elicited the expected pattern of activation of frontoparietal regions and decreased activation of the amygdala (Supplemental Figure 1). Our primary hypothesis was that maltreated children who exhibited greater

modulation of the amygdala during reappraisal (i.e., lower amygdala activity during reappraisal relative to passive viewing of negative stimuli) would be at lower risk for developing depression. To evaluate this hypothesis, we examined whether reappraisal-related amygdala modulation moderated the association between child maltreatment and depression symptoms and observed a significant maltreatment-by-brain function interaction (b=4.20, t=2.41, p=.018). Greater reappraisal-related amygdala modulation predicted lower risk for depression at follow up among maltreated youth but had no relationship to depression among those without a history of maltreatment (Figure 2), suggesting that the ability to modulate amygdala responses using cognitive reappraisal may be a marker of resilience. This finding remained significant after numerous sensitivity analyses (e.g., including pubertal stage as a covariate rather than age, including IQ as a covariate) and survived correction for multiple comparisons. Greater information on the analytical approach and sensitivity analyses can be found in *Supplemental Materials.*

** FIGURE 2 **

To follow up this finding, we conducted a set of exploratory analyses examining whether reappraisal-related recruitment of prefrontal regions moderated the association between child maltreatment and depression symptoms. To do so, we examined a set of prefrontal regions that were engaged during reappraisal relative to passive viewing of emotional stimuli in the whole sample (Supplemental Figure 1). This analysis revealed a significant maltreatment-by-brain function interaction in two regions consistently implicated in cognitive reappraisal (50): the right superior frontal gyrus (SFG by maltreatment interaction: b=-3.11, t=-2.50, p=.014) and right dorsal anterior cingulate cortex (dACC by maltreatment interaction: b=-2.65, t=-1.95, p=.052).

In both cases, greater recruitment during reappraisal predicted lower depression symptoms at baseline, but only for those with a history of maltreatment (Figure 3). Due to the exploratory nature of these analyses, the results presented here were not corrected for multiple comparisons. However, these patterns persist in multiple sensitivity analyses examining additional covariates (see *Supplemental Materials*).

FIGURE 3

Finally, we assessed of whether greater use of cognitive reappraisal as an emotion regulation strategy in everyday life moderated the association between child maltreatment and depression symptoms. Again, we observed a significant maltreatment-by-use interaction in the expected direction (b=-0.044, t=-2.420, p=.017), whereby the association between severity of child maltreatment and depression symptoms was weaker among those who reported greater use of cognitive reappraisal (Figure 4). This finding suggests that not only is the efficacy of cognitive reappraisal associated with resilience to depression following child maltreatment, but also the tendency to use reappraisal techniques in everyday life.

** FIGURE 4 **

Discussion

The ability to modulate negative emotion using cognitive control strategies may represent a resiliency marker, which protects against depression in children who have experienced adversity. The current report finds evidence of such a relationship. Specifically, greater capacity to modulate amygdala activation using cognitive reappraisal predicts decreasing levels of depressive symptoms across a two-year follow-up period. Similarly, greater recruitment of

prefrontal regions also predicts lower concurrent symptoms of depression among children with history of maltreatment. Finally, maltreated children who reported a greater tendency to use reappraisal as a coping strategy in everyday life have lower levels of depressive symptoms than those who did not. Of note, in youth unexposed to maltreatment, neither amygdala modulation, prefrontal function, nor reported use of cognitive reappraisal in daily life related to symptoms of depression. These preliminary findings support the proposed model of resilience. This model underscores specific neurobiological factors involved in the cognitive control of emotion as a potential protective factor buffering children who have experienced adversity from negative outcomes later in life.

Examining these questions in a youth sample is particularly advantageous, as insights about mechanisms of resilience can be leveraged to inform early interventions. Additionally, studies examining resilience to psychopathology in adulthood following childhood adversity often reflect differences in the accumulation of environmental stressors over the life course and suffer from recall biases that are mitigated, at least somewhat, when studying resilience in closer proximity to the initial source of adversity. The major contribution from the current study relates to the contrast of brain-behavior associations in youth with and without maltreatment. Specific neural markers of effective cognitive reappraisal only related to depressive symptoms in children with a history of maltreatment. As such, the current study delineated a marker of resilience.

Resilience involves many dynamic and interacting factors that modulate risk in the face of adversity (24), including cultural (25), familial (27), and genetic factors (29). The current study leverages advances in developmental cognitive neuroscience to examine brain function supporting specific cognitive processes as a mechanistic path to resilience. An analysis of resilience on this neural-psychological level is advantageous as it can be used to identify

malleable targets for preventing the onset or progression of internalizing disorders. This approach has been successfully undertaken in the context of anxiety and posttraumatic stress disorders, wherein basic mechanistic understanding of threat-related biases in information processing and associated neural functioning has shaped therapeutic approaches (e.g., attention bias modification therapy, ABMT) aimed at mitigating anxiety and trauma-related symptoms (30, 112–115). ABMT was designed to explicitly target the types of attentional biases towards threat that characterize anxiety disorders by training subjects to orient attention away from threatening cues in the task (116, 117). As such, it is a model of how basic understanding of neurobiological mechanisms can directly inform preventative and treatment approaches (30, 114, 118).

Similar translational approaches leveraging neurocognitive understanding of cognitive reappraisal could be useful in preventative and intervention efforts aimed at mitigating risk for internalizing disorders, especially in children who have experienced adversity. Cognitive reappraisal is a core intervention technique central to evidence-based psychotherapy practices for depression and anxiety, such as cognitive behavioral therapy (CBT) (42). Moreover, CBT for depression and anxiety has been associated with changes in frontoamygdala neural circuitry, including reductions in amygdala hyperresponsiveness and increased engagement of medial and lateral regions of the prefrontal cortex during both resting state and task performance (119, 120). Further, our findings show that in addition to cognitive reappraisal ability, the tendency to use it in everyday life may also serve as an important buffer for depression following adversity. Therefore, clinicians may incorporate training geared towards scaffolding and encouraging the use of reappraisal in the daily lives of children exposed to adversity. These strategies may be a

useful component of early interventions designed to prevent the onset of internalizing psychopathology following adversity.

The present study was designed to test the proposed framework that the neurobiological underpinnings of emotion regulatory capacity may serve as a buffer against the negative mental health outcomes typically associated with adversity. However, this study should be considered in light of its limitations and the unresolved questions that remain. We focus specifically on outcomes related to early life experiences of threat or maltreatment. Given the highly overlapping experiences of maltreatment and neglect, it is important to make note that children who experience other forms of adversity, such as deprivation or neglect, could also benefit from the protective effects of successful recruitment of regulatory circuitry. Similarly, we have focused on a specific form of cognitive control of emotion—cognitive reappraisal—it is possible that other forms of cognitive control of emotion, such as acceptance of emotional experiences, may modulate negative emotional experiences and the associated amygdala response in a similar way. Future work should investigate the boundary conditions of this model of resilience and determine whether other strategies of emotional regulation may also function as a protective factor buffering children exposed to various forms adversity from development of psychopathology. In addition, the aim of the current study was to determine resilience factors. However, the finding that emotion regulation does not benefit those without a history of maltreatment is interesting and may reflect differential etiological mechanisms of depression in those with and without a history of maltreatment, as proposed by Teicher and colleagues (121). Finally, these analyses identified markers of resilience that were specific to symptoms of depression and not anxiety, which may reflect factors specific to depression (e.g., rumination over past events) that are more readily reframed using reappraisal, as opposed to anxious worries

that have yet to occur. Nonetheless, this divergence provides an important target for future research.

Conclusion

Exposure to child adversity is a potent risk factor for depression and anxiety. Here, we argue that the ability to recruit frontoparietal control networks to modulate amygdala reactivity to negative cues may be a protective factor that buffers children from developing internalizing problems following exposure to adversity. Our findings are consistent with this possibility, demonstrating that children who are more able to modulate amygdala reactivity and recruit prefrontal regions of the frontoparietal network during cognitive reappraisal are less likely to exhibit symptoms of depression following exposure to maltreatment—pointing to a potential neurobiological mechanism of resilience. Greater efforts to identify resilience factors at the neural and behavioral levels can provide mechanistic translational targets for interventions aimed at preventing or treating psychopathology among children who have experienced adversity.

Figure and Table Legends

Table 1. Summary of Participant Demographic and Clinical Characteristics

Figure 1. Schematic representation of experimental task. While undergoing fMRI, participants were instructed to either look at an emotional image (neutral or negative) or attempt to decrease their emotional response using cognitive reappraisal (negative images only). Following the presentation of the image, participants reported the strength of emotion they experienced while viewing the image. Between trials, participants were instructed to relax.

Figure 2. Amygdala activity during cognitive reappraisal moderates the association between child maltreatment and depression symptoms over time. A. Red mask overlay shows left amygdala ROI. B. Greater reduction in amygdala activation during cognitive reappraisal relative to passive viewing of negative emotional stimuli (decrease negative > look negative) is associated with lower depression symptoms over time among children who were maltreated (blue) but is unrelated to the development of depression symptoms among those without a history of maltreatment (black). Shaded region indicates 95% CI.

Figure 3. Association of child maltreatment with depression is moderated by prefrontal recruitment during cognitive reappraisal. A. Red mask overlay shows right superior frontal gyrus (SFG) ROI. B. Greater recruitment of the right SFG during cognitive reappraisal relative to passive viewing of negative emotional stimuli (decrease negative > look negative) is associated with reduced symptoms of depression among children exposed to maltreatment (blue) but is unrelated to depression symptoms among those without a history of maltreatment (black). C. Red mask overlay shows right dorsal anterior cingulate cortex (dACC) ROI. D. Greater recruitment of the right dACC during cognitive reappraisal relative to passive viewing of negative emotional stimuli (decrease negative > look negative) is associated with reduced symptoms of depression among children exposed to maltreatment (blue) but is unrelated to depression symptoms among those without a history of maltreatment (black). Shaded region indicates 95% CI.

Figure 4. Association between reported tendency to engage in cognitive reappraisal in daily life and depression is moderated by severity of abuse history. Greater reported use of cognitive reappraisal strategies in response to stressful life events is associated with lower symptoms of depression, particularly among children with more severe maltreatment history (blue) compared to those with a less severe or no history of maltreatment (black). Reappraisal use measured using the Emotion Regulation Questionnaire (ERQ) (38). Shaded region indicates 95% CI.

Neurobiological Markers of Resilience to Depression Following Childhood Maltreatment: The Role of Neural Circuits Supporting the Cognitive Control of Emotion

Supplemental Information

Supplemental Methods

Participants

160 participants aged 8-17 (M=12.76, SD=2.62) drawn from a larger parent study were recruited from schools, after-school and prevention programs, adoption programs, food banks, shelters, parenting programs, medical clinics, and the general community in Seattle, WA between January 2015 and June 2017. Participants were recruited based on inclusion criteria for the maltreated group, including exposure to physical or sexual abuse or direct witnessing of domestic violence (i.e., violence directed towards a caregiver), while participants in the control group were required to have an absence of exposure to maltreatment or other forms of interpersonal violence and were matched to children in the maltreated group on age, sex, and handedness. Exclusion criteria included IQ < 80, pervasive developmental disorder, active psychotic symptoms, mania, substance abuse, other safety concerns, as well as any standard contraindications for MRI scanning (e.g., braces). Approximately half of the sample was female (50.3%) and 45.0% of the sample identified as White, 23.2% as Black, 10.6% as Hispanic/Latino, 11.3% as Asian or Pacific Islander, and 9.9% as biracial or other racial/ethnic groups.

Of the 160 children who initially completed the neuroimaging assessment, 9 were excluded from analysis due to either: excessive motion during scanning (n=2), lack of behavioral responding in more than 2 runs of the emotion regulation task (n=2), failure to complete the task (n=4), and exposure to significant violence that was not maltreatment-related (n=1). All procedures were

ACCEPTED MANUSCRIPT

approved by the Institutional Review Board at the University of Washington. Written informed consent was obtained from legal guardians while children provided written assent.

Measures

History of Maltreatment. Children and parents were assessed for history of exposure to emotional, sexual, or physical abuse using a multi-informant, multi-method approach to determine participants' exposure to maltreatment. Children were classified as experiencing emotional, physical, or sexual abuse if it was endorsed by the child or parent on the following: Childhood Experiences of Care and Abuse (CECA) interview (1), UCLA PTSD Reaction Index (PTSD-RI) trauma screen (2), Violence Exposure Scale for Children-Revised (VEX-R) (3), Childhood Trauma Questionnaire (CTQ) (4, 5), the Juvenile Victimization Questionnaire (JVQ) (6), or PTSD-RI trauma screen. Domestic violence was assessed by child-report only on the CECA interview and PTSD-RI. Validated thresholds for exposure to physical and sexual abuse (5) were applied to determine abuse exposure based on the CTQ. Children were classified as experiencing physical or sexual abuse if abuse was endorsed by the child (on the CECA interview, PTSD-RI trauma screen, or above the validated CTQ threshold) or parent (on the JVQ or PTSD-RI trauma screen). A total of 79 children (51.7%) experienced maltreatment, of whom 46% experienced sexual abuse, 72% physical abuse, and 56% emotional abuse. While the recruitment focus of this sample was to recruit youth exposed to threat-related adversity in the form of violence, other types of adversity, such as neglect, commonly co-occur with abuse and this polyvictimization was reflected in our sample with 24% experiencing neglect. Inter-rater reliability was good for child and caregiver maltreatment reports (82.0% agreement; kappa=0.62). A maltreatment severity score was created by summing the total number of types of maltreatment and violence exposure experienced by the

ACCEPTED MANUSCRIPT

child, including physical abuse, sexual abuse, emotional abuse, domestic violence, and exposure to violence in the broader community. Each type of maltreatment or violence exposure was coded as present or absent, and these indicators were summed to create a severity score.

Depression Symptoms. Symptoms of depression were measured using the Children's Depression Inventory (CDI) (7). This self-report questionnaire is a 27-item measure that is widely used and validated for use in children aged 8-17. Each question probes a specific symptom that is answered at three levels of severity (i.e., "once in a while," "many times," "all the time"). These items were summed for a total score at baseline and at the follow-up visit approximately two years later (M=20.33 months, SD=6.98 months). Similar to previous studies of reliability and validity (7), the CDI demonstrated good internal consistency in the current sample (Cronbach's alpha=.89).

Anxiety Symptoms. Symptoms of anxiety were measured using the Screen for Child Anxiety Related Emotional Disorders (SCARED) (8), which measures anxiety symptoms across five domains: panic/somatic, generalized anxiety, separation anxiety, social phobia, and school phobia. The SCARED has good psychometric properties (8) and had excellent internal consistency in the current sample (Cronbach's alpha = .94). This measure was collected at baseline and at the follow-up visit.

Emotion Regulation Strategies. Tendency to employ reappraisal in everyday life following stressful events was assessed using the Emotion Regulation Questionnaire (ERQ) (9). The ERQ is a widely used 10-item self-report questionnaire, with subscales for specific emotion regulation strategies (e.g., reappraisal). Answers are given on a seven-point Likert scale, from "strongly disagree" to "strongly agree." The internal consistency was good in the current sample (Cronbach's alpha = .84).

ACCEPTED MANUSCRIPT

Procedure

Emotion Regulation Task. Participants completed an experimental task designed to evoke cognitive reappraisal which has been widely used in adults (10) and adapted for use in pediatric samples (11, 12). Age-appropriate negative and neutral images from a stimulus set developed in the lab of the senior author (KAM) were used (images and normative ratings are publicly available: https://osf.io/43hfq/). Participants were trained on the emotion regulation task at a previous study visit and instructions were reviewed in the scanner. For 'Look' trials participants were trained to attend to the picture and to allow their emotional reaction to unfold naturally. During 'Far' trials (hereafter referred to as Regulation) participants were trained to modulate their emotional response to negative images using cognitive reappraisal. Participants were taught two reappraisal strategies prior to the scan: psychological distancing (e.g. "imagine the situation as far away from you,") and reinterpretation (e.g. "imagine the situation is fake or not real," or "pretend the people in the picture are just actors in a movie"). Following image presentation participants were asked to rate the intensity of their emotional response on a 'feelings thermometer' ranging from 0 to 3. Length of stimulus presentation (6-10 seconds) and inter-trial interval (ITI) were jittered (2-6 seconds). Participants completed 4 runs of the task, each run consisting of 5 Look Neutral, 5 Look Negative, and 5 Regulation (i.e., Far Negative) trials, resulting in 20 trials of each condition across the 4 runs of the task. Negative images in Look and Regulation trials were matched on valence and arousal. Trials were presented in random order within each run.

Image Acquisition and Preprocessing. All images were acquired using a Phillips Achieva 3T scanner using a 32-channel head coil at the University of Washington's Integrated Brain Imaging Center. Anatomical scans (T1-weighted MPRAGE volumes; TR=2530ms, TE=3.5ms, flip angle=7°, FOV=256×256, 176 slices, in-plane voxel size=1mm^3) were acquired for co-registration

ACCEPTED MANUSCRIPT

with functional magnetic resonance imaging (fMRI). Blood oxygenation level dependent (BOLD) signal during functional runs was acquired using a gradient-echo T2*-weighted echo planar imaging (EPI) sequence. 37 3mm thick axial slices were acquired sequentially and parallel to the AC-PC line (TR=2s, TE=25ms, flip angle=79°, Inter-slice gap=.6mm, FOV=224×224×132.6, matrix size=76x74). Prior to each scan, four images were acquired and discarded to allow longitudinal magnetization to reach equilibrium.

Data preprocessing consisted of the following steps: motion correction with FSL MCFLIRT, slice timing correction with FSL slicetimer, despiking with AFNI 3dDespike, and spatial smoothing with FSL SUSAN (using a Gaussian kernel size of 6-mm FWHM) (13–15). Nuisance regressors entered into person-level models consisted of 6 rigid-body motion regressors as well as time-series extracted from white matter and ventricles entered to control for physiological noise (16). Outlier volumes in which framewise displacement exceeded 1 mm, the derivative of variance in BOLD signal across the brain (DVARS) exceeded the upper fence (above 75th percentile + 1.5 x inter-quartile range), or signal intensity was more than 3 SD from the mean were excluded by regressing these volumes out of first-level models. This resulted in a total of 285 frame displacements (M=0.181, SD=0.153, average of 2.22% frames) for the non-maltreatment group and 310 frame displacements (M=0.240, SD=0.219, average of 3.93% frames) for the maltreatment group, which was not significantly different (t(149)=1.901, p=.060). Following estimation of the individual-level models, the resulting contrast images were registered first to a custom template, representing the average anatomy of the sample, and then from the custom template to the standard space of the Montreal Neurological Institute (MNI) template. Anatomical co-registration of the functional data with each participant's T1-weighted image and normalization were performed using Advanced Normalization Tools (ANTs) (17).

ACCEPTED MANUSCRIPT

Statistical Analysis

fMRI. Event-related regressors were created by convolving a boxcar function of phase, duration, and amplitude one with the standard (double-gamma) hemodynamic response function for each phase of the task (i.e., instruction, stimulus, rating). Regressors for stimulus presentation were separated by trial type (Look Neutral, Look Negative, Regulation). A general linear model was constructed for each participant and the two contrasts used in prior studies of this task (19–21) were examined: Look Negative > Neutral (i.e., emotional reactivity), and the Regulation > Look Negative (i.e., emotion regulation). Individual-level estimates of BOLD activity were submitted to group-level random effects models using FSL's FLAME 1 (21) with cluster-level correction of $z > 2.3$, $p < .01$. We examined differences in BOLD response during contrasts of interest in whole-brain analyses to confirm expected effects of the experimental task (see Supplemental Table S1).

Amygdala ROI Analysis. We examined amygdala activation using a region-of-interest (ROI) analysis, separately for left and right amygdala. Functional ROIs were created by intersecting a structural mask of the amygdala from the Harvard-Oxford subcortical atlas (20% threshold) with the map of activation in the entire sample for each contrast. Linear regression models were computed with depression symptoms at baseline and follow up as the outcome measure, amygdala activation during regulation, history of trauma and their interactions as predictors, while controlling for socioeconomic status (i.e., income to needs ratio), non-white status, sex, and age. When examining follow up depression as the outcome of interest, days between baseline and follow up and baseline symptoms of depression were also included as covariates. Analyses were repeated for anxiety symptoms.

ACCEPTED MANUSCRIPT

Exploratory Prefrontal ROI Analysis. We examined prefrontal activation using separate ROI analyses for each of the regions of the prefrontal cortex that were identified in whole-brain analyses of Regulation (Decrease Negative > Look Negative). Functional ROIs were created by intersecting a structural mask of frontal regions from the Harvard-Oxford subcortical atlas (50% threshold) with the map of activation in the entire sample during reappraisal, resulting in 9 prefrontal ROIs listed in Supplemental Table S2, including the superior frontal gyrus, middle frontal gyrus, inferior frontal gyrus, frontal pole, and dorsal anterior cingulate cortex. Linear regression models were computed with depression symptoms at baseline and follow up as the outcome measure, prefrontal activation during regulation, history of trauma and their interactions as predictors, while controlling for socioeconomic status, non-white status, sex, and age. All predictors were mean-centered. When examining follow up depression as an outcome of interest, days between baseline and follow up and baseline symptoms of depression were also included as covariates. Analyses were repeated for anxiety symptoms.

Daily Emotion Regulation Strategy. To evaluate whether daily use of reappraisal moderated the association of maltreatment with depression, we estimated a linear regression model with baseline and follow-up depression as the outcome, reappraisal tendency, abuse severity, and their interactions as predictors, controlling for socioeconomic status, non-white status, sex, and age. When examining follow up depression, days between baseline and follow up and baseline symptoms of depression were also included as covariates. Analyses were repeated for anxiety symptoms.

ACCEPTED MANUSCRIPT

Supplemental Results

Behavioral Task Effects

When examining task performance across the entire group, participants rated negative pictures (M=1.62, SD=0.64) as more emotionally evocative than neutral pictures (M=0.18, SD=0.36; $t(150)=28.1$, $p<.001$), as expected. In addition, subjective ratings indicated that participants had significantly lower affective responses to negative pictures following the appraisal conditions (M=1.24, SD=0.68) as compared to passively looking at negative pictures ($t(150)=10.86$, $p<.001$), giving confidence that subjects performed the task successfully. When examining whether subjective reports of reappraisal moderates the relationship between maltreatment and depression, effects are specific to amygdala modulation and are not associated with subjective ratings of affect, which is consistent with prior work from our lab and others (12, 22). More specifically, the relationship between maltreatment and risk for depression is not moderated by reductions in subjective affect ratings during reappraisal (interaction term: $b=-0.928$, $t=-0.316$, $p=.753$).

Whole-brain Task Effects

Across the entire sample, the use of cognitive reappraisal elicited the expected pattern of activation of frontoparietal regions and decreased activation of the amygdala when compared to passive viewing of negative emotional stimuli (Supplemental Figure S1).

ACCEPTED MANUSCRIPT

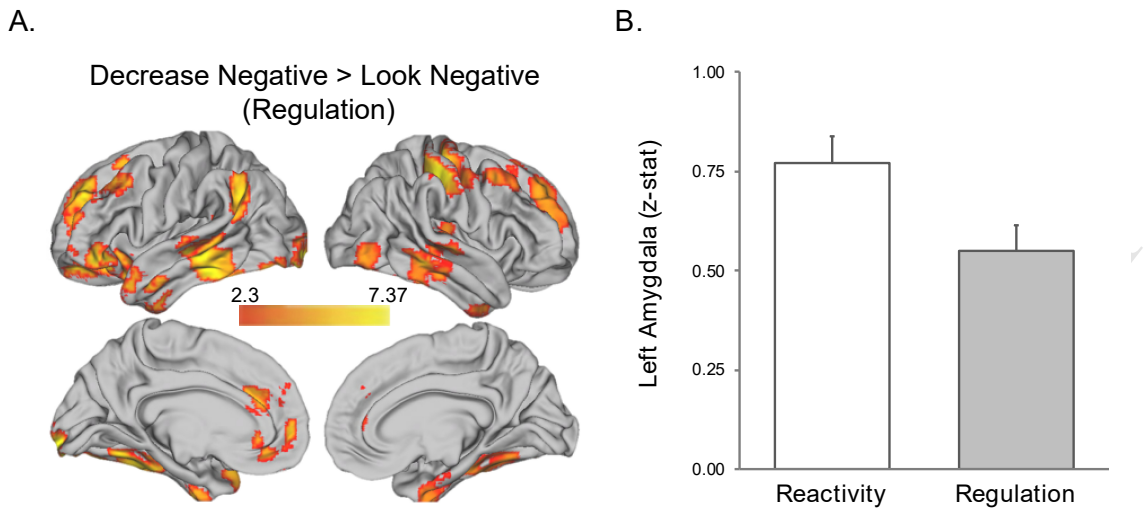

Figure S1. Neural activity during cognitive reappraisal. A. Regions that show increased functional recruitment during cognitive reappraisal relative to passive viewing of negative emotional stimuli (decrease negative > look negative). Note: Cluster-level correction applied in FSL, $z > 2.3$ was the primary threshold, and $p < .01$ was the cluster-level threshold. Color bar indicates magnitude of z-statistic B. Extracted z-stats from left amygdala ROI shows modulation of activation during passive viewing (reactivity; white bar) and reappraisal (regulation; gray bar) of negative compared to neutral images for illustrative purposes. Error bars indicate standard error of the mean.

Group Differences

Findings indicated no group differences in the extent of amygdala modulation during reappraisal (t(149)=-0.163, p=.871), recruitment of prefrontal ROIs (rSFG: t(149)=1.359, p=.176, rdACC: t(149)=0.600, p=.549), or tendency to engage in reappraisal day-to-day (t(149)=-0.118, p=.906). However, compared to those with no history of maltreatment, youth with history of maltreatment reported less reductions in subjective affect when engaging in reappraisal compared to passive viewing of negative pictures (history of maltreatment: M=-0.244, SD=0.391; no history: M=-0.524, SD=0.420; independent t-test: t(149)=4.241, p<.001).

ACCEPTED MANUSCRIPT

Primary ROI Resilience Analysis

When examining the relationship between emotion regulation efficacy and risk for future depression, results revealed a that participants' ability to modulate amygdala reactivity during reappraisal moderated the relationship between maltreatment history and depression scores at follow up. After controlling for sex, age, number of days between baseline and follow up visits, and baseline CDI depression score, CDI depression score at follow up was significantly associated with the interaction between left amygdala activation during reappraisal (Decrease Negative > Look Negative) and maltreatment history (b=4.20, t=2.41, p=.018). Aside from baseline depression (b=0.670, t=7.560, p<.001), no other covariates significantly predicted follow-up depression (ps>.05). This pattern of resilience was not evident for anxiety symptoms or baseline depression (ps>.05). Findings suggest that greater reappraisal ability, as indexed by successful amygdala modulation, may buffer maltreated youth from negative effects of adversity and lower risk for future depression.

Exploratory ROI Analysis

We sought to explore whether engagement of prefrontal regions during reappraisal moderated the relationship between maltreatment and psychopathology. Findings revealed that activation of the right superior frontal gyrus (SFG) and right dorsal anterior cingulate cortex (dACC) moderated the relationship between history of maltreatment and current depression (activation-by-maltreatment interaction SFG: b=-3.11, t=-2.50, p=.014; dACC: b=-2.65, t=-1.95, p=.052). Aside from maltreatment history (b=7.025, t=4.825, p<.001) and age (b=0.704, t=3.349, p=.001), no other covariates significantly predicted current depression (ps>.05). This interaction was not

ACCEPTED MANUSCRIPT

evident for other exploratory frontal ROI regions, anxiety symptoms, or follow up depression (*p*s>.05).

Daily Emotion Regulation Strategy

When examining daily tendency to use emotion regulation strategies, findings showed that reappraisal tendency significantly moderated the relationship between abuse severity and baseline depression (*b*=-0.044, *t*=-2.420, *p*=.017). The main effect of maltreatment severity (*b*=2.326, *t*=4.522, *p*<.001) and age (*b*=0.589, *t*=3.094, *p*=.002) were also significantly related to baseline depression. This pattern was not observed for anxiety symptoms or follow up depression (*p*s>.05).

Effects of Age and Sex

When examining the impact of age on reappraisal, our findings indicated that age has no significant effect on brain function during cognitive reappraisal in the ROIs implicated in resilience. Specifically, the main effect of age on amygdala modulation during reappraisal is not significant (*b*=0.017, *t*=0.802, *p*=.424) and neither is the effect of age on recruitment of prefrontal regions during reappraisal (right SFG: *b*=-0.032, *t*=-1.171, *p*=.243; right dACC: *b*=-0.023, *t*=-0.933, *p*=.352). While age was not related to the reported tendency to engage in daily reappraisal (*b*=0.257, *t*=1.124, *p*=.263), age was significantly associated with subjective ratings of affect modulation during the reappraisal task (*b*=-0.027, *t*=-2.078, *p*=.040), wherein older participants reported greater reductions in negative affect during regulation.

To examine sex effects, we computed independent t-tests for each ROI implicated in resilience with sex as the between-subjects factor. While there was no significant main effect of sex on amygdala modulation or recruitment of the right dACC (*p*s>.499), recruitment of the right

ACCEPTED MANUSCRIPT

SFG differed significantly between males and females (t(149)=-2.048, *p*=0.042), wherein males recruited to a greater degree than females (males: M=0.342, SD=0.872; females: M=0.052, SD=0.865). All analyses reported in the manuscript control for age and sex, in addition to socioeconomic status and race, as nuisance regressors.

Cross-measure Correlations

Trait-level tendency to use reappraisal (ERQ) is not correlated with subjective reports of reappraisal success, amygdala modulation or right SFG recruitment during reappraisal (*p*s>.05). It is, however, significantly correlated with recruitment of the right dACC during reappraisal (r(149)=.17, *p*=0.043). Amygdala modulation during reappraisal is correlated with recruitment of the right SFG (r(149)=.18, *p*=.029) and dACC (r(149)=.18, *p*=.020; Supplemental Table S3).

Sensitivity Analyses

Correction for Multiple Comparisons. P-values were corrected using the *p.adjust* package in R by controlling for the false discovery rate using the Benjamini–Hochberg method (23). Our primary analysis examining whether children with history of maltreatment, in particular, are protected from risk for depression by successful down-modulation of amygdala during reappraisal was corrected for 2 comparisons (right and left amygdala) and the significant interaction in the left amygdala survived correction for multiple comparisons (*p*=.035). Exploratory analyses in the prefrontal ROI regions were corrected for 9 comparisons (see Supplemental Table S2 for all prefrontal ROIs) and initial findings did not survive correction (*p*s>.123).

Controlling for Medication Use. Any participants taking short-acting medications, such as ADHD medications, abstained from taking medication on the day of the scan. Nonetheless, some

ACCEPTED MANUSCRIPT

participants were on other psychotropic medications that could not be temporarily discontinued, and we have conducted all key analyses controlling for medication status (i.e., taking medication on day of scan). When recomputing the interaction effect of amygdala modulation and history of maltreatment on follow up depression, findings remain significant (b=4.25, t=2.450, p=.016) when controlling for medication use. Similarly, findings examining prefrontal recruitment during reappraisal also remain significant (rSFG: b=-3.047, t=-2.490, p=.014; rdACC: b=-2.560, t=-1.974, p=.050).

Pubertal Effects. We have also conducted sensitivity analyses that include pubertal status as measured by the Tanner scale instead of age as a covariate. Key findings remained largely the same. However, the finding that activation in the prefrontal ROI right dACC interacts with maltreatment history to predict baseline depression changed from significant to trending towards significance (p=.08) in the same direction and pattern. Thus, we conclude that these findings are generally robust.

Controlling for IQ. Finally, we conducted all analyses controlling for IQ. Key findings remained largely the same, though the finding that activation in the prefrontal ROI right dACC interacts with maltreatment history to predict baseline depression changed from significant to marginally significant (p=.06) in the same direction and general pattern. Thus, findings are generally robust to controlling for IQ.

rdACC ROI Sensitivity Analyses. The right dACC ROI contains a cluster that is fairly posterior to other clusters in that ROI. However, according to the Harvard-Oxford Atlas, this cluster resides in the ACC. Nonetheless, we have computed the right dACC findings without this cluster as a sensitivity analysis and results indicate that findings hold at a marginally significant level of p=.06 in the same pattern of findings.

Maternal mediation, stress inoculation, and the development of neuroendocrine stress resistance in primates

Karen J. Parker*, Christine L. Buckmaster, Karan Sundlass, Alan F. Schatzberg, and David M. Lyons

Edited by Bruce S. McEwen, The Rockefeller University, New York, NY, and approved January 3, 2006 (received for review August 1, 2005)

The stress inoculation hypothesis presupposes that brief intermittent stress exposure early in life induces the development of subsequent stress resistance in human and nonhuman primates. Rodent studies, however, suggest a role for maternal care rather than stress exposure per se (i.e., the maternal mediation hypothesis). To investigate these two hypotheses, we examined maternal care and the development of stress resistance after exposure to brief intermittent infant stress (IS), mother–infant stress (MIS), or no stress (NS) protocols administered to 30 monkeys between postnatal weeks 17 and 27. Unlike rodents, the IS condition did not permanently increase primate maternal care, nor did measures of total maternal care predict subsequent offspring hypothalamic–pituitary–adrenal-axis responsivity. Although MIS infants received less maternal care than IS and NS infants, both IS and MIS monkeys developed subsequent stress resistance. These findings indicate that rearing differences in the development of stress resistance are more closely related to differences in prior stress exposure than to differences in maternal care. A second experiment confirmed this conclusion in a different cohort of 25 monkeys exposed as infants to high foraging-demand (HFD) or low foraging-demand (LFD) conditions. HFD infants exhibited intermittent elevations in cortisol levels and received less maternal care than LFD infants. In keeping with a key prediction of the stress inoculation hypothesis, HFD males responded to stress in adulthood with diminished hypothalamic–pituitary–adrenal-axis activation compared with LFD males. Results from both experiments demonstrate that stress inoculation, rather than high levels of maternal care, promotes the development of primate stress resistance.

hypothalamic–pituitary–adrenal axis | monkey | maternal care | resilience

People with the capacity to maintain healthy emotional functioning in the aftermath of stressful experiences are said to be resilient, or stress resistant (1, 2). Researchers have sought to identify attributes associated with stress resistant individuals, with the expectation that understanding the etiology of stress resistance may lead to the prevention of stress-related psychiatric disorders. One intriguing finding to emerge from this retrospective research has been that stress resistance is associated with childhood exposure to mildly stressful events (1, 3). Prospective longitudinal studies of nonhuman primates support this finding, because monkeys exposed to brief, 1-h periods of maternal-separation stress exhibit diminished anxiety and attenuated hypothalamic–pituitary–adrenal (HPA)-axis responses to subsequent stressors compared with unmanipulated monkeys (4).

Little is known about the psychobiological mechanisms that promote the development of stress resistance in human or nonhuman primates, but studies of rodents suggest a possible role for maternal care. Similar to monkeys, neonatal rodents exposed to brief repeated maternal separations of 3–15 min in duration (i.e., postnatal handling) exhibit diminished emotionality and attenuated HPA-axis responses to subsequent stressors (5, 6). The development of rodent stress resistance is thought to be maternally mediated (7), because brief intermittent separations stimulate increased maternal licking and grooming not only at reunion but across pup development (8). These permanent changes in maternal behavior increase the expression of glucocorticoid receptors in the hippocampus, thereby enhancing sensitivity to glucocorticoid-feedback inhibition during stress exposure later in life (5). Importantly, the emotional and neuroendocrine stress resistance observed in briefly separated rodents can be replicated in unmanipulated offspring that naturally receive high levels of maternal care during development (9). That increased maternal care is sufficient to produce stress resistance in rodents is corroborated by evidence that the amount of maternal stimulation received by pups during development is negatively correlated with later stress-induced HPA-axis activation (9, 10).

The utility of rodent research in modeling the etiology of human stress resistance is limited, however, by critical developmental differences in rodent and primate HPA-axis physiology. The brief maternal separation paradigm coincides with the rodent stress-hyporesponsive period (SHRP), during which time mice and rats do not respond, or respond only weakly, to mild stressors with HPA-axis activation (11, 12). High levels of maternal stimulation maintain the pup's SHRP status, with removal of maternal regulation resulting in gradual disinhibition of HPA-axis activity. Diminished maternal stimulation that fails to adequately inhibit activation of the pup's HPA-axis during the SHRP, as documented for longer maternal separations of 3 h in duration (13), promotes stress hyperresponsivity later in life. Although it has not been systematically studied, human and nonhuman primate infants do not appear to exhibit a SHRP and are capable of exhibiting stress responses throughout lifespan development (14–17). Primate infants, unlike rodent pups, respond to brief intermittent maternal separations with immediate HPA-axis activation (18) and develop subsequent neuroendocrine stress resistance even after maternal separations of 4–6 h in duration (19). If the same psychobiological mechanisms "program" the stress response in rodents and primates, HPA-axis activation during primate development should lead to later stress hyperresponsivity. Yet, in primates, a paradigm that induces anxiety and activates the HPA-axis leads, instead, to emotional and neuroendocrine stress resistance (4, 19).

An alternative to the maternal mediation hypothesis is the stress inoculation hypothesis, which is based on the notion that mild stress, and the acute anxiety and HPA-axis activation that it engenders, is necessary for the development of subsequent stress resistance. Several theorists have likened the development of stress resistance to acquired immunity (1, 3). Immunity, whether naturally occurring or therapeutically induced by inoc-

ulation, derives from exposure to a mild version of a pathogen that strengthens immunological resistance. Similarly, early exposure to mild stress may "inoculate" the developing organism, thereby enhancing resistance to subsequent stressors. In the following experiments, we investigated the roles of maternal mediation and stress inoculation in the development of stress resistance in squirrel monkeys.

Experiment 1

The goals of this experiment were twofold: (*i*) to determine whether brief intermittent separations permanently increase primate maternal behavior during development, and (*ii*) to test whether maternal care received during development predicts subsequent offspring HPA-axis responsivity. Thirty infants from three rearing conditions were studied. In the first condition, only infants were exposed to brief intermittent separations from the natal group for 10 weekly 1-h sessions [infant stress (IS)]. In the second condition, mothers and infants were removed together from the natal group and exposed to an otherwise identical stress protocol [mother–infant stress (MIS)]. Both IS and MIS protocols acutely induce anxiety and activate the HPA-axis in young monkeys (18, 20). In the third condition, mothers and infants remained undisturbed in their natal groups [no stress (NS)]. Maternal care was assessed every other week during three distinct periods in the home cage (i.e., before stress exposure, immediately after stress exposure, and 24 h after stress exposure). Eleven weeks after completion of the rearing protocols, a 30-min novelty stress test was administered to examine rearing differences in offspring HPA-axis responsivity.

Research has shown that IS infants develop neuroendocrine stress resistance, whereas NS infants do not (19). The maternal-mediation hypothesis therefore predicts that IS infants will consistently receive more maternal care than NS infants. Although it is unknown whether MIS infants develop stress resistance, this condition was included because maternal stress diminishes primate maternal care (21). If MIS infants receive less or equal amounts of maternal care compared with control infants, the maternal mediation hypothesis predicts that MIS infants will not develop neuroendocrine stress resistance. The stress inoculation hypothesis, in contrast, predicts the development of neuroendocrine stress resistance in all offspring exposed to brief intermittent stress protocols, because these protocols acutely induce anxiety and activate the HPA-axis.

Results. ***Rearing differences in the frequency and duration of maternal behavior.*** Rearing protocols did not permanently alter the frequency or duration of any maternal behavior measure across development, because no rearing differences were evident in the periods immediately before or 24 h after stress exposure. Several transient effects were observed immediately after stress exposure, however, including a main effect of rearing condition on the duration of dorsal contact (i.e., the species-typical infant riding posture on the mother's shoulders and upper back) ($F_{2,26} = 5.304$, $P = 0.012$). Upon returning to the home cage, IS infants spent more time clinging to their mothers than did NS infants (39 ± 3 vs. 19 ± 6 min; $P = 0.011$). IS infants also clung to their mothers more than did MIS infants (MIS = 26 ± 4 min), but this difference failed to reach statistical significance. MIS and NS infants did not differ from one another. A significant protocol-week by rearing-condition interaction was found for nursing duration immediately after stress exposure ($F_{8,104} = 4.37$, $P = 0.004$). However, post hoc tests at each week revealed no consistent rearing differences, because both IS and MIS infants differed from NS infants (and not each other) at only two of the five time points (i.e., weeks 3 and 5). These data indicate that IS infants generally received more maternal care than NS infants immediately after stress exposure, whereas MIS infants did not significantly differ from either group.

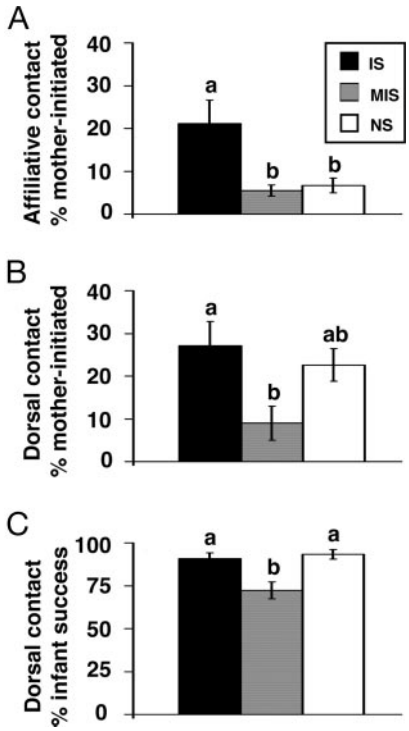

Fig. 1. Rearing differences in mother–infant social transactions. Affiliative (*A*) and dorsal (*B*) contact attempts initiated by mothers relative to infants and total infant-initiated dorsal contact attempts accommodated by mothers (*C*) are presented as mean ± SEM for monkeys previously exposed to IS ($n = 11$), MIS ($n = 10$), or NS ($n = 9$) rearing conditions. Groups without shared letters differ significantly ($P < 0.05$), whereas groups with shared letters do not.

Rearing differences in mother–infant social transactions. Enduring rearing differences in mother–infant transactions were observed across all three observation period types (Fig. 1). A significant effect of rearing condition was found for the percentage of total affiliative contact attempts initiated by mothers relative to their infants ($F_{2,26} = 4.964$, $P = 0.015$). IS mothers made more affiliative contact attempts (21%) than either MIS (6%; $P = 0.02$) or NS (7%; $P = 0.049$) mothers, whereas MIS and NS mothers did not differ. Similarly, rearing differences were found for the percentage of total dorsal contact attempts initiated by mothers relative to infants ($F_{2,26} = 3.787$, $P = 0.036$). IS mothers initiated dorsal contact with infants 27% of the time, whereas MIS mothers initiated dorsal contact only 9% of the time ($P = 0.043$). Although NS mothers' dorsal contact initiatives more closely resembled those of IS mothers (23%), they did not significantly differ from either group. Finally, a rearing difference in the percentage of total infant-initiated dorsal contact attempts that were accommodated by mothers was found ($F_{2,26} = 8.340$, $P = 0.002$). MIS infants' attempts to attain dorsal contact were accommodated 72% of the time, whereas IS and NS infants dorsal contact attempts were, respectively, accommodated 91% ($P = 0.009$) and 93% ($P = 0.003$) of the time. These results indicate that, across observation periods, MIS infants received diminished maternal care relative to IS and, at times, NS infants.

Neuroendocrine stress responsivity and maternal care. Rearing differences were found for baseline cortisol levels ($F_{2,26} = 10.739$, $P < 0.0001$), such that both IS ($P = 0.048$) and MIS ($P < 0.0001$) offspring exhibited diminished baseline cortisol levels compared with NS offspring. To control for these differences, baseline cortisol levels were used as a statistical covariate to analyze rearing differences in poststress cortisol levels. Consistent with

PSYCHOLOGY

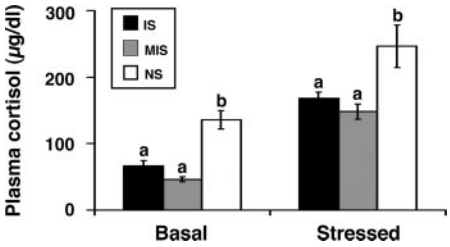

Fig. 2. Plasma cortisol levels at baseline and after stress exposure are presented as mean ± SEM for juvenile monkeys previously exposed to IS (n = 11), MIS (n = 10), or NS (n = 9) rearing conditions. Groups without shared letters (a, b) differ significantly ($P < 0.05$).

the stress inoculation hypothesis, rearing differences in stress resistance were observed ($F_{2,25} = 5.124$, $P = 0.014$). Specifically, previously stress-exposed IS ($P = 0.033$) and MIS ($P = 0.013$) offspring exhibited diminished cortisol responses to the novelty stress test compared with NS offspring (Fig. 2).

Total maternal care did not predict subsequent offspring cortisol levels at baseline or after novelty stress exposure. Although enduring rearing differences in several social-transaction measures were found, as was a transient increase in dorsal contact immediately after stress exposure, none of these measures predicted subsequent baseline- or stress-levels of cortisol. Nursing duration in the period immediately after stress exposure, however, did predict cortisol levels at baseline [$\beta = -0.525$ (df = 28); $P = 0.003$] and after novelty stress exposure [$\beta = -0.397$ (df = 28), $P = 0.030$]. To test the hypothesis that nursing duration mediates the effects of rearing condition on baseline- and stress-levels of cortisol, nursing duration and rearing condition were examined together as independent variables in the same regression equation (22, 23). Rearing-related differences in baseline ($F_{2,26} = 4.79$, $P = 0.017$) and stress ($F_{2,26} = 3.86$, $P = 0.034$) levels of cortisol remained significant, whereas nursing duration no longer predicted either cortisol measure. These results do not support a role for nursing as a mediator of the effect of rearing condition on cortisol levels.

Experiment 2

Findings from experiment 1 suggest that rearing differences in neuroendocrine stress resistance are more closely related to differences in prior stress exposure than to differences in maternal care. The primary goal of experiment 2 was to assess the generality of these findings by testing the maternal mediation and stress inoculation hypotheses in 25 monkeys exposed to a different type of mild early life stress. The protocols used in this experiment consisted of high foraging-demand (HFD) and low foraging-demand (LFD) conditions that differed in the effort required by mothers to obtain food. These daily foraging protocols did not alter infant growth, weight, nursing behavior, or solid-food consumption, but HFD infants exhibited intermittently elevated cortisol levels and received diminished maternal care compared with LFD infants across development (24, 25).

At 8 years of age, monkeys were restrained in primate chairs for two 30-min sessions that were administered 7 days apart. An intramuscular injection of saline was given 60 min before the first restraint test to examine rearing differences in HPA-axis responsivity and poststress recovery. Because neuroendocrine stress resistance in rats arises from enhanced glucocorticoid-feedback regulation of the HPA-axis stress response (5), we also tested in this experiment whether the same was true for monkeys. Thus, exogenous cortisol (i.e., 2.5 mg/kg hydrocortisone sodium succinate) was intramuscularly injected 60 min before the second restraint test. This dose of hydrocortisone inhibits stress-induced increases in squirrel monkey adrenocorticotropic hormone

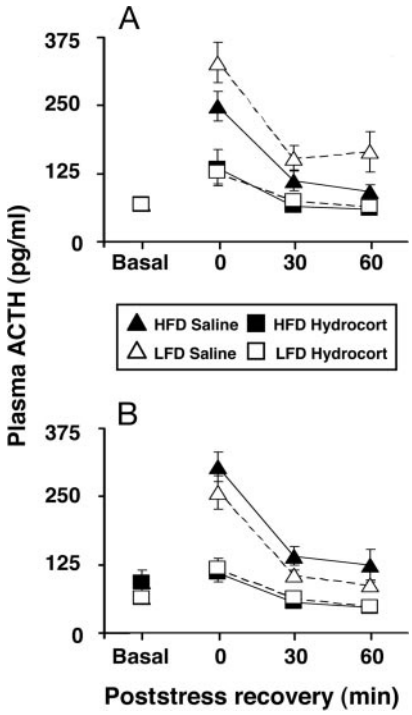

Fig. 3. Plasma ACTH levels after pretreatment with saline or hydrocortisone 0, 30, and 60 min after stress exposure are presented as mean ± SEM for male (*A*) and female (*B*) monkeys previously exposed to HFD (n = 6 males, 6 females) or LFD (n = 7 males, 6 females) rearing conditions.

(ACTH) (26) and was used to assess rearing differences in glucocorticoid-feedback inhibition of the HPA-axis stress response.

The maternal mediation and stress inoculation hypotheses make different predictions about HPA-axis responsivity in HFD and LFD monkeys. The maternal mediation hypothesis predicts that the diminished maternal behavior and elevated cortisol levels that characterize the HFD condition will promote increased stress responsivity in HFD compared with LFD monkeys. Conversely, the stress inoculation hypothesis predicts that the mild stress and elevated cortisol levels that typify the HFD condition will produce stress resistance in HFD but not LFD monkeys.

Baseline ACTH and cortisol levels did not vary across repeated samples, nor did either differ by rearing condition. Although no effect of gender on baseline ACTH levels was found, gender did influence baseline cortisol levels ($F_{1,21} = 14.785$, $P = 0.001$). Specifically, females had baseline cortisol levels that were 2-fold higher than males (186 ± 24 vs. 87 ± 9).

A significant rearing-condition by gender interaction across the saline-pretreatment poststress sample time points for ACTH was found ($F_{1,20} = 4.476$, $P = 0.047$). Further analysis revealed a main effect of rearing condition on stress responsivity for male, but not female, monkeys (Fig. 3). Although ACTH levels decreased significantly over time in all monkeys ($F_{2,40} = 22.461$, $P < 0.0001$), only adult males previously exposed to the HFD condition responded to restraint stress with diminished ACTH levels compared with males from the LFD condition ($F_{1,10} = 6.253$, $P = 0.031$). This rearing effect was also apparent for time-integrated poststress measures of ACTH in male ($F_{1,10} = 5.851$, $P = 0.036$), but not female, monkeys.

Unlike ACTH, cortisol levels after the saline pretreatment continued to rise significantly across the poststress measurement period. In keeping with the gender differences in baseline cortisol levels described above, time-integrated poststress mea-

sures of cortisol in females (306 ± 25 μg/dl) were 67% greater than in males (184 ± 14 μg/dl; $F_{1,21} = 18.358$, $P < 0.0001$). However, the magnitude of poststress increases in cortisol levels above baseline did not differ by gender. Cortisol levels at 0, 30, and 60 min after stress were, respectively, 68 ± 8, 100 ± 10, and 118 ± 8 μg/dl higher than baseline for males, and 79 ± 26, 126 ± 23, and 148 ± 26 μg/dl higher than baseline for females. No significant gender or rearing effects on poststress cortisol levels were discerned.

As expected, the hydrocortisone pretreatment robustly suppressed stress levels of ACTH relative to the saline pretreatment (Fig. 3). Hydrocortisone suppressed time-integrated poststress levels of ACTH in both males ($F_{1,11} = 99.83$, $P < 0.0001$) and females ($F_{1,10} = 69.47$, $P < 0.0001$). Within 30 min of stressor termination, ACTH levels were equal to or less than baseline in all monkeys, and glucocorticoid-feedback inhibition did not differ significantly by rearing condition.

Discussion

Findings from experiment 1 indicate that, unlike rodents, brief maternal separations do not permanently increase primate maternal behavior, nor does total maternal care predict later offspring HPA-axis stress responsivity. Although young MIS infants receive less maternal care across development than IS or NS infants, both IS and MIS monkeys develop stress resistance. Despite the fact that nursing duration in the period immediately after stress exposure predicted later cortisol measures, subsequent analyses did not support a role for nursing as a mediator of the effect of rearing condition on cortisol levels. These findings suggest that rearing differences in the development of stress resistance are more closely related to differences in prior stress exposure than to differences in maternal care. Experiment 2 confirmed these findings in a second cohort of monkeys exposed to a different type of mild early life stress. HFD infants exhibit modestly elevated cortisol levels and receive less maternal care than LFD infants during development. As adults, HFD males subsequently demonstrate diminished stress-induced HPA-axis activation compared with LFD males. Results from these two experiments suggest that stress inoculation, rather than high levels of maternal care, promotes the development of primate stress resistance.

Our findings from monkeys parallel data from rabbits that indicate that brief separations from the natal nest, independent of maternal care, are sufficient to produce stress resistance. Mother rabbits provide minimal maternal care, however, and stress resistance develops in briefly separated rabbit pups whether they are raised with or without their mothers (27). In contrast, stress resistance does not develop in motherless monkeys (28) or orphaned children (29). Combined with findings from rodent studies reviewed above, this collective evidence suggests that species differences in parental behavior (i.e., minimal vs. extensive) and HPA-axis development (i.e., presence vs. absence of the SHRP) may determine how stress resistance is programmed on a species-by-species basis.

The notion that high levels of maternal care are not required to produce stress resistance does not negate the critical role of parenting in primate development nor does it indicate that aspects of lifelong health are impervious to parental care. Indeed, mother–infant attachment relationships were firmly established before the initiation of both of our experiments, and all infants received adequate maternal care, well within the range of what is typical for squirrel monkeys (30). In humans, socioemotional support derived from close relationships clearly promotes effective coping (31). It seems likely, then, that some threshold amount of maternal care during or after stress exposure is required to bolster the young primate's coping capacity, thereby contributing to the development of stress resistance.

The importance of maternal care notwithstanding, results from our studies implicate a role for stress inoculation in the development of primate stress resistance. Whether these findings reflect specific or general stress inoculation effects merits consideration. Specific inoculation refers to the notion that exposure to a given stressor confers subsequent resistance to the same or similar stressor. General inoculation, in contrast, refers to the notion that prior exposure to one stressor strengthens resistance to a variety of stressors (4). In experiment 1, the IS and MIS protocols and the subsequent stress resistance test had several elements in common. These elements include exposure to an unfamiliar environment and separation from the natal group. IS monkeys, however, also exhibit emotional stress resistance in their home cage in the presence of the natal group (4) and demonstrate enhanced performance on an emotionally challenging cognitive test compared with NS monkeys (32). There were, likewise, considerable differences between the HFD protocol and the restraint test used in experiment 2. Although further research is required to determine whether mild early life stress exposure also confers resistance to subsequent stressors of a physiological nature (e.g., immune challenge or insulin-induced hypoglycemia), the initial results from our experiments point to some form of general stress inoculation.

Several rearing-related discrepancies were apparent both between and within experiments. A rearing difference in baseline cortisol levels, for example, was found in experiment 1 but not experiment 2. This disparity is likely attributable to age, because rearing differences in baseline cortisol levels become less detectable over development (32) and are no longer discerned by the late-juvenile period (ref. 19; and K.J.P., K. L. Rainwater, C.L.B., A.F.S., S. E. Lindley, and D.M.L., unpublished work). It is not clear why this change occurs, nor is the function of this rearing effect understood. A second disparity was evident within experiment 2. Significant rearing differences in ACTH, but not cortisol, levels were found in adult male monkeys after restraint-stress exposure. In the hour after restraint stress termination, ACTH levels steadily decreased toward baseline, whereas cortisol levels continued to rise. Because the adrenal response to stress temporally follows that of the pituitary, it is likely that our assessment period was too short to capture rearing differences in adrenal recovery. The restraint test as used in experiment 2 thus appears more suitable for detecting rearing differences in the temporal dynamics of primate pituitary compared with adrenal stress physiology.

Several gender differences were found in experiment 2. These include 2-fold higher cortisol levels in adult females compared with males at baseline and after stress exposure and demonstration of neuroendocrine stress resistance only in adult males. Stress resistance is reliably expressed equally in males and females throughout adolescence (19), but evidence from experiment 2 indicates that gender differences in stress resistance may emerge after the peripubertal period. Higher baseline glucocorticoid levels and enhanced stress responsivity have been reported for adult female rats and humans, and ovarian steroids are thought to modulate both phenomena (33, 34). In contrast, androgens, which are more prevalent in adult males than females, inhibit HPA-axis activation (35). One might conclude that pubertal changes in specific gonadal steroid levels may contribute to gender differences in adult stress resistance. An alternative possibility is that stress-inoculated female monkeys do not "lose" their stress resistant status at puberty, but rather, ovarian hormones and elevated baseline cortisol levels mask this phenomenon at certain points in the ovarian cycle. Careful monitoring of ovarian function in cycling and noncycling adult females with respect to HPA-axis physiology is required to accurately test whether female stress resistance persists into adulthood.

Neuroendocrine stress resistance in rodents is mediated, in part, by enhanced glucocorticoid-feedback sensitivity (5), but we

failed to find a similar effect in primates. These results suggest that the neural basis of stress resistance in primates may differ from that in rodents. This possibility has important implications for guiding future research, particularly in humans, which more closely resemble monkeys than rats. It should be noted, however, that only one dose of hydrocortisone was used in our study. Although the dose was carefully selected based on previous research (26), examination of multiple hydrocortisone doses is required to more fully evaluate rearing differences in primate sensitivity to glucocorticoid negative feedback.

A final topic that warrants comment is that the skewed sex ratio in experiment 1 (23 females and 7 males) limits the generalizability of the cortisol and maternal care data to males. In a separate cohort, however, IS compared with NS males were previously shown to exhibit diminished stress-induced cortisol levels (19). We likewise documented in experiment 2 that, similar to MIS males, mildly stressed HFD males that received less maternal care than control males in infancy develop subsequent stress resistance. Aspects of experiment 1 nevertheless remain to be replicated, especially the effects of maternal care on subsequent HPA-axis stress responsivity in IS and NS male monkeys.

In conclusion, it is likely that certain forms of primate stress resistance arise from manageable exposure to mild stress that stimulates anxiety and activates the HPA-axis. This formulation presupposes that anxiety and HPA-axis activation during stress exposure play key roles in promoting the development of stress resistance. With continued investigation of this hypothesis, a comprehensive understanding of the etiology and neurobiology of stress resistance may ultimately provide a foundation for improved treatment and prevention of stress-related psychiatric disorders.

Methods

Experiment 1. ***Subjects.*** Thirty squirrel monkey infants (*Samiri sciureus*) were born at Stanford University and served as subjects. Subjects were housed in wire-mesh cages (1.8 × 1.2 × 1.8 m) in 10 natal groups composed of three to four mother–infant dyads. Group composition was determined primarily by birth date to minimize developmental differences between cohabitating infants. Monkeys were housed on a 12/12 h light/dark cycle in rooms with an ambient temperature of 26°C. Cages were cleaned daily, and monkeys had ad libitum access to water, food, and toys. A sliding door in each home cage facilitated access to a portable capture cage. Monkeys were trained to enter the capture cage to facilitate experimental manipulations. All procedures were approved by Stanford University's Administrative Panel on Laboratory Animal Care.

Rearing protocols. Subjects remained undisturbed in their natal groups through postnatal week 16, at which time natal groups were assigned to one of three conditions. The IS condition included 11 offspring (7 females and 4 males). From postnatal weeks 17–27, each infant was removed from its mother and natal group for a 1-h period once a week, placed in a cage (46 × 46 × 46 cm) adjacent to unfamiliar monkeys in a different room, and temporarily deprived of all forms of maternal and natal-group contact. After the 1-h separation period, each infant was returned to the home cage. No more than one infant from each natal group was separated on a given day, and all manipulations occurred between 1400 and 1800 h. The MIS condition included 10 offspring (8 females and 2 males). This rearing protocol was identical to the IS protocol in all ways, except that each infant and its mother were removed together for the 1-h period. In the third condition, nine offspring (eight females and one male) remained undisturbed as NS controls.

Behavioral observations. Each IS and MIS mother–infant dyad was observed during three distinct 15-min periods in the home cage: (*i*) before stress exposure, (*ii*) immediately after stress exposure, and (*iii*) 24 h after stress exposure. These observations were conducted for the first, third, fifth, seventh, and ninth stress exposures, for a total of 15 observation periods per dyad. Observations of NS mother–infant dyads occurred at matched time points to facilitate comparisons between rearing conditions.

Squirrel monkey mothers, unlike rodent mothers, do not lick or groom their infants. An established squirrel monkey ethogram was thus used to select maternal behavior measures (30). During postnatal weeks 17–27, infants are attaining physical, if not psychological, independence from their mothers. Infants at these ages locomote independently, consume solid foods, and nurse infrequently (36). Although no longer in constant physical contact, mothers still provide maternal care and engage in a variety of complex social interactions with their infants.

By using a computer-aided recording program, mother–infant behavior was collected by a trained observer. Durations of a given behavior were calculated by summing the elapsed period between initiation and termination. Bouts of a given behavior were distinct if separated by at least 3 seconds. The following measures were summarized for each observation period: (*i*) dorsal contact (infant observed in the species-typical riding posture on the mother's shoulders and upper back), (*ii*) affiliative contact (mother and infant observed in side-by-side huddling), and (*iii*) nursing contact (infant observed in the species-typical ventral nursing position). A composite measure of maternal care was created by combining dorsal, affiliative, and nursing contact scores.

Social transactions between mothers and infants were also recorded for each observation period (24). Transactions were initiated by attempts to change the immediate state of association between two individuals by means of either make-or-break dorsal contact initiatives or make-or-break affiliative contact initiatives. Successful attempts were scored whenever make-or-break contact initiatives were accommodated by the target. Failed attempts were scored when either initiative by an actor was resisted by the target.

Neuroendocrine stress responsivity and hormone quantification. At an average of 38 weeks of age, a 30-min novelty stress test was administered to examine rearing differences in offspring HPA-axis responsivity. Each mother–offspring dyad was transported to a cage (60 × 60 × 90 cm) in an unfamiliar room that did not contain other monkeys. Both the cage and room used for stress testing were different from those used for the rearing protocols. Tests occurred between 1500 and 1800 h.

Blood samples were collected from offspring 10 days before the experimental manipulations to establish cortisol measures in an undisturbed state. Blood samples were also collected immediately after testing to examine cortisol levels after novelty exposure, and a subset of these data was reported in ref. 4. All blood samples were collected between 1530 and 1800 h to control for circadian variation (37). Femoral blood samples were collected within 3 minutes of capture from manually restrained monkeys with single-use syringes containing 20 μl of ethylenediamine tetraacetic acid. Each sample was transferred to a chilled tube and centrifuged at 4°C, and the plasma fraction was stored at −80°C. Cortisol was measured in duplicate by using an established radioimmunoassay as described in ref. 37.

Data analysis. The effects of rearing condition on mother–infant-behavior measures and cortisol levels were assessed with ANOVA. Rearing condition and gender were between-subjects factors, and protocol week (1, 3, 5, 7, and 9), and observation period (before stress exposure, immediately after stress exposure, and 24 h after stress exposure) were within-subjects, repeated-measures factors. The Geisser–Greenhouse correction was used to adjust for multiple comparisons across repeated-measures factors. Tukey post hoc comparisons were used to discern significant rearing differences. Simple and multiple linear-regression models were used to investigate whether ma-

ternal behavior predicted offspring cortisol levels and to test whether rearing condition effects on cortisol levels were mediated by maternal behavior, respectively (22, 23). All test statistics were evaluated with two-tail probabilities ($P < 0.05$), and descriptive statistics are presented as mean ± SEM.

Experiment 2. ***Subjects, rearing protocol, and subsequent husbandry.*** Twenty-five squirrel monkeys born at Stanford University served as subjects. Subjects were housed under standard laboratory conditions in eight natal groups, each composed of three to four mother–infant dyads. Groups were randomized at 10 weeks of age to HFD (six male and six female infants) or LFD (seven male and six female infants) rearing conditions. The HFD condition consisted of 120% (by weight), and the LFD condition consisted of 600% (by weight) of normal daily food intake buried in foraging boards as described in detail in ref. 24. These foraging protocols were administered daily and lasted 12 weeks. All monkeys were housed under standard laboratory conditions thereafter. Mothers were removed after weaning at 36 weeks, and offspring were housed with two to three same-sex peers.

Neuroendocrine stress responsivity and hormone quantification. At an average of 8.4 years of age, adult monkeys were restrained for two separate 30-min sessions in a standard primate chair. Chair restraint allows for slight movement and does not induce pain or inflict tissue damage (26). Restraint stress was used because adult squirrel monkeys do not respond to novelty stress as robustly as do infants (38). Tests were administered during the breeding season, when females exhibit ovarian hormone cyclicity, to best approximate adult human physiology (39).

The first test was preceded 60 min earlier by an intramuscular injection of saline to examine rearing differences in HPA-axis stress responsivity. Seven days later, an intramuscular injection of exogenous cortisol (i.e., 2.5 mg/kg hydrocortisone sodium succinate; Upjohn, Kalamazoo, MI) was likewise administered 60 min before the second test to examine rearing differences in glucocorticoid-feedback inhibition of the HPA-axis stress response.

Immediately after completion of each test, blood samples were collected, and monkeys were returned to the home cage. Additional samples were then collected 30 and 60 min later to provide posttest measures of recovery. Blood samples were also collected from otherwise undisturbed monkeys in the home cage 7 days before and 7 days after experimental manipulations to assess baseline hormone levels.

Blood samples were obtained as described in experiment 1 between 1330 and 1430 h to control for circadian variation (37). Plasma levels of ACTH and cortisol were measured in duplicate by using established radioimmunoassays (37). The cortisol assay does not distinguish between endogenous and exogenous cortisol (i.e., hydrocortisone), and, therefore, ACTH levels served as the primary index of stress responsivity and glucocorticoid-feedback regulation (26).

Data analysis. Baseline hormone measures were analyzed for rearing condition, gender, and time effects by using repeated-measures ANOVA. Time-integrated poststress hormone measures were determined with the trapezoidal rule to estimate the area under each monkey's saline and hydrocortisone time course curve (26). Time course (0, 30, and 60 min after restraint) and time-integrated poststress measures were then analyzed for rearing condition, gender, and hydrocortisone-pretreatment effects with baseline hormone levels controlled as a statistical covariate. All test statistics were evaluated with two-tailed probabilities ($P < 0.05$), and descriptive statistics are presented as mean ± SEM.

We thank Dr. Seymour Levine, Dr. Shelly Flagel, and Michael Heller for their thoughtful comments on this manuscript and Dr. Helena Kraemer for statistical guidance. The genesis of new cells, including neurons, in the adult human brain has not yet been demonstrated. This study was undertaken to investigate whether neurogenesis occurs in the adult human brain, in regions previously identified as neurogenic in adult rodents and monkeys. Human brain tissue was obtained postmortem from patients who had been treated with the thymidine analog, bromodeoxyuridine (BrdU), that labels DNA during the S phase. Using immunofluorescent labeling for BrdU and for one of the neuronal markers, NeuN, calbindin or neuron specific enolase (NSE), we demonstrate that new neurons, as defined by these markers, are generated from dividing progenitor cells in the dentate gyrus of adult humans. Our results further indicate that the human hippocampus retains its ability to generate neurons throughout life.

1998 Nature America Inc. • http://medicine.nature.com

Loss of neurons is thought to be irreversible in the adult human brain, because dying neurons cannot be replaced. This inability to generate replacement cells is thought to be an important cause of neurological disease and impairment. In most brain regions, the generation of neurons is generally confined to a discrete developmental period. Exceptions are found in the dentate gyrus and the subventricular zone of several species that have been shown to generate new neurons well into the postnatal and adult period[1–6]. Granule neurons are generated throughout life from a population of continuously dividing progenitor cells residing in the subgranular zone of the dentate gyrus in the rodent brain[5]. 'Newborn' neurons generated from these progenitor cells migrate into the granule cell layer, differentiate, extend axons and express neuronal marker proteins[7–10].

We examined whether progenitor cells reside in the adult human hippocampus and whether new neurons are born within the dentate gyrus of the adult human brain. Postmortem tissue from the hippocampus and the subventricular zone of caudate nucleus was obtained from cancer patients (n = 5) who received one intravenous infusion (250 mg; 2.5 mg/ml, 100 ml) of bromodeoxyuridine (BrdU) for diagnostic purposes[11]. One patient diagnosed with a similar type and location of cancer, but without BrdU treatment, was included as a control. A thymidine analog, BrdU is incorporated into the DNA of dividing cells and can be detected immunohistochemically in their progeny[5,12,13].

Cell genesis and survival in the adult human dentate gyrus

The number of surviving labeled, proliferating progenitors was

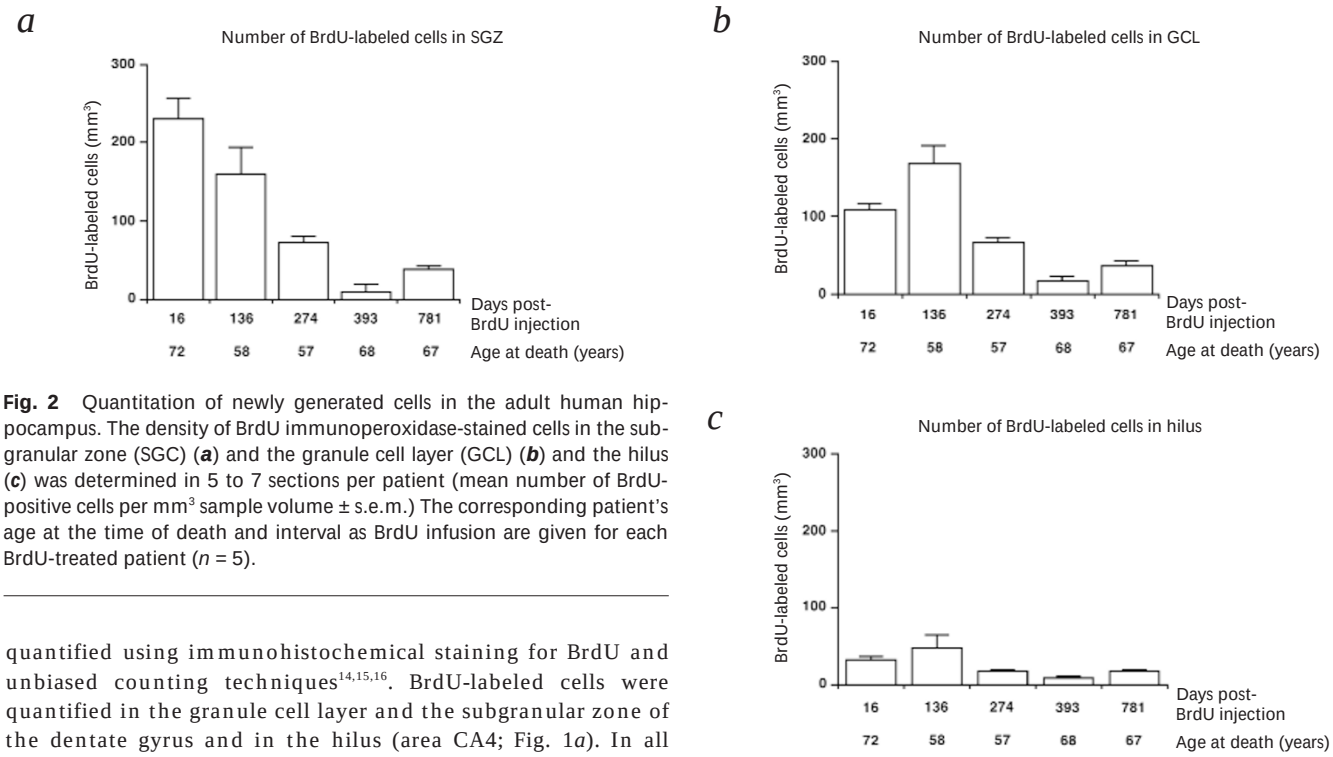

Fig. 2 Quantitation of newly generated cells in the adult human hippocampus. The density of BrdU immunoperoxidase-stained cells in the subgranular zone (SGC) (***a***) and the granule cell layer (GCL) (***b***) and the hilus (***c***) was determined in 5 to 7 sections per patient (mean number of BrdU-positive cells per mm^3 sample volume ± s.e.m.) The corresponding patient's age at the time of death and interval as BrdU infusion are given for each BrdU-treated patient (n = 5).

quantified using immunohistochemical staining for BrdU and unbiased counting techniques[14,15,16]. BrdU-labeled cells were quantified in the granule cell layer and the subgranular zone of the dentate gyrus and in the hilus (area CA4; Fig. 1*a*). In all BrdU-treated patients, the granule cell layer contained BrdU-positive, round- to oval-shaped nuclei with the typical morphology of granule cell neuron nuclei (Fig. 1*b–d*). The morphological appearance and localization of these nuclei were similar to those of the nuclei of cells found in the dentate gyrus of adult mouse, rat and marmoset monkey[5,6,17]. No BrdU-immunoreactive profiles could be detected in the control patient that had not received BrdU. The presence of BrdU-positive nuclei in a brain region that is neurogenic in many other mammalian and primate species indicates that proliferating neural progenitor cells are present in the adult human dentate gyrus.

The number of BrdU-positive cells in the granule cell layer, the subgranular zone and hilus varied between individuals, as may be expected because of the varying post-infusion intervals and different ages of the patients (Fig. 2*a–c*). There is an apparent decline in the number of cells that are detected in the patients that had the longest interval between BrdU treatment and histological assessment. This decline may indicate a progressive death of the newly generated cells over time. However, the small sample weakens any quantitative conclusion.

BrdU-labeled cells co-express neuronal markers

To determine the cell fate of the BrdU-immunoreactive cells, we did triple immunofluorescent labeling for BrdU and cell-specific markers, including glial fibrillary acidic protein (GFAP), a marker for astroglia, and one of the neuronal markers, NeuN[18,19], calbindin[20] or neuron specific enolase[21] (NSE). Confocal microscopy was used to determine the phenotype of the BrdU-positive cells (Figs. 3 and 4). No evidence for cross-reactivity between GFAP-immunoreactivity and any of the three neuronal markers was detected in these sections. GFAP-immunopositive processes were observed to surround neurons and their processes, but did not co-express in the same cell (Fig. 3*e–h*). Autofluorescence was observed in this tissue, but the nonspecific emission artifact was easily detected by its contribution to multiple wavelengths (Fig. 3*a–d*). We took care to evaluate potential sources of autofluorescence in the human tissue by directly imaging untreated sections and sections from the control patient both with and without the pretreatment for BrdU-immunohistochemical detection in the absence of antibodies against BrdU. The autofluorescence was present even in completely untreated sections and was restricted to the cytoplasm of neuronally marked cells or to endothelial cells and red blood cells and could be clearly distinguished from BrdU-immunoreactive profiles (Fig. 3). The majority of the NeuN-positive neurons that double-labeled with BrdU were located within or near the granule cell layer and had the morphological characteristics of granule cell neurons: round or oval nuclei with small- to medium-sized cell bodies (Fig. 3). Confocal microscopic Z-series analyses of BrdU-positive nuclei unambiguously identified double-labeling with NeuN and demonstrated the existence of newly generated (BrdU-labeled) granule cell neurons in the dentate gyrus of the adult human brain (Fig. 3*d–h*). The phenotypic expression of these BrdU-positive neurons in adult humans was equivalent to the expression found in adult rodents[5,10,12,17] (Fig. 3*i–l*). The average fraction of BrdU-NeuN double-labeled cells in the granule cell layer was 22.0 ± 2.4% among the BrdU-treated patients.

Neurons double-labeled with BrdU and NSE could also be detected in all BrdU-treated subjects (Fig. 4*e–f*). The average fraction of BrdU-labeled cells that were also NSE-labeled in the granule cell layer was 22.7 ± 2.8%. Cells that double-labeled for BrdU and calbindin were also observed and provided further support for the occurrence of neurogenesis in the adult SGZ, GCL and hilus (Fig. 4*a–d*). The average fraction of BrdU-labeled cells that were also calbindin-positive in the granule cell layer was 7.9 ± 2.2% among the BrdU-treated patients. The dentate gyrus from all individuals contained a fraction of BrdU-positive cells that were also GFAP-positive, 18.1 ± 1.8%, and had the typical morphology of star-shaped glial cells with small, irregularly shaped nuclei and small cell bodies with thin, GFAP-positive processes (Fig. 4*c–d*). The dentate gyrus from all subjects contained BrdU-

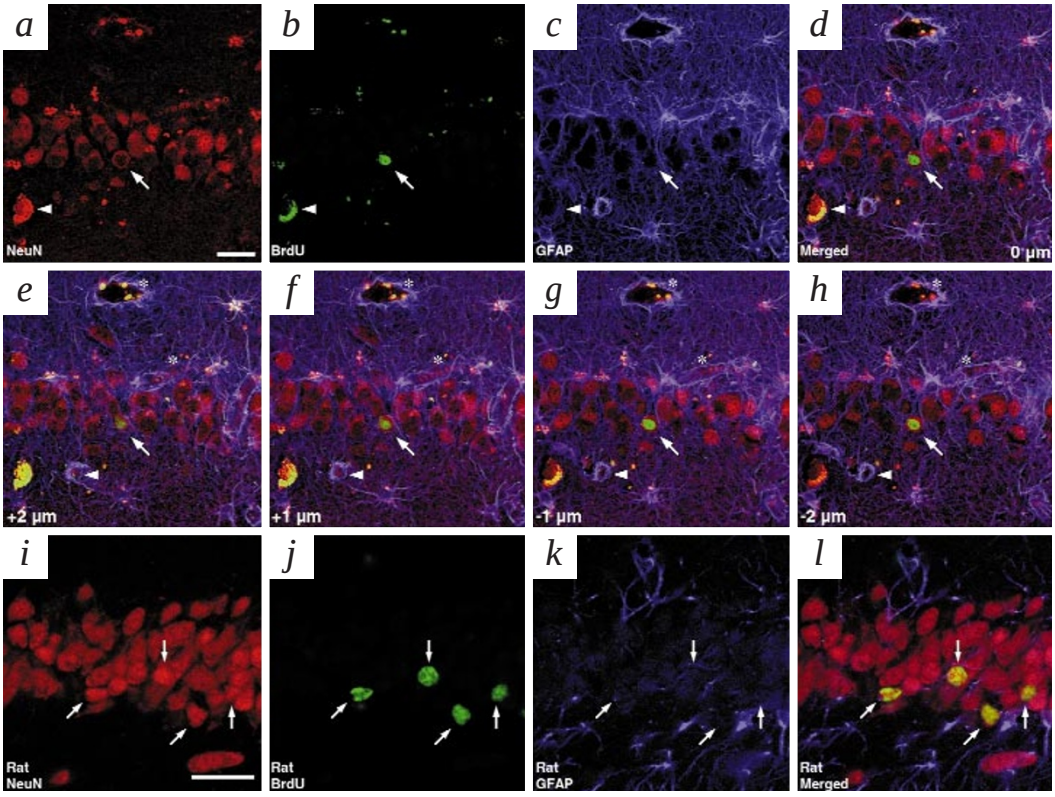

Fig. 3 Newly generated cells in the adult human dentate gyrus can express a neuronal phenotype. Simultaneous detection of immunofluorescent labels for NeuN (***a***; scale bar represents 25 µm), BrdU (***b***) and GFAP (***c***) for detection of astrocytes and a merge of these signals in x-, y- and z-registration (***d***) examined by confocal microscopy showed that BrdU-labeled nuclei could specifically co-express NeuN without expressing GFAP (arrows in *a*–*d*). In addition to specific BrdU-labeling, some neurons contained nonspecific fluorescence in the green and red emission, reflecting their accumulation of lipofuchsin granules (arrowheads in *a*–*d*). Red blood cells and endothelial cells, present in several small blood vessels, also emit nonspecific green and red fluorescence (small blood vessel indicated by arrowheads, larger blood vessels indicated by asterisks in *e*–*h*). The specificity of BrdU-NeuN co-expression in three-dimensions is demonstrated by a series of focal planes above (***e***,***f***) and below (***g***, ***h***) the focal plane shown in *d* (arrows indicate the same cell as in *d*). The appearance of adult BrdU-positive neurons in the human dentate gyrus is equivalent to BrdU-labeled neurons in the adult rat dentate gyrus (***i***–***l***; scale bar represents 25 µm). The rat tissue (*i*–*l*) is at a different magnification than the human tissue (*a*–*h*).

positive cells that were immunonegative for both neuronal and glial markers. These immunonegative cells likely represent quiescent undifferentiated cells, newborn cells of a phenotype not examined here and/or a pool of asymmetrically dividing progenitor cells. These cells were characterized by small, round-to-oval BrdU-positive nuclei and the absence of cell-specific immunoreactivity.

To further confirm the presence of neurogenesis, we double-labeled using antibodies against BrdU and either NSE, calbindin or NeuN with chromagens for brightfield optics (alkaline phosphatase (Vector Blue) for BrdU and 3-amino-9-ethylcarbazole (AEC) for the neuronal markers). Although confocal microscopy could not be used for imaging, the brightfield chromagens had the advantage of not fading with examination and not contributing autofluorescence to the image. Examination of brightfield staining confirmed that BrdU-positive cells in the adult human hippocampus could express a neuronal phenotype (Fig. 5*a*–*e*) morphologically indistinguishable from adult rodent BrdU-positive neurons (Fig. 5*f* and *g*), strongly supporting our conclusion that neurogenesis occurs in the dentate granule cell layer of the adult human brain.

BrdU labeling in the subventricular zone of adult human brain

Another neurogenic region, the subventricular zone (SVZ) adjacent to the caudate nucleus, was examined for the presence of BrdU-positive cells. Tissue samples from all BrdU-treated patients contained BrdU-positive cells within the SVZ (Fig. 1*e*–*f*). BrdU-positive cells did not co-express the cell-specific markers GFAP and NeuN (data not shown). The morphology of BrdU-labeled nuclei within the SVZ was small and round-to-oval, resembling that of progenitor cells in the rat SVZ (ref. 5). This finding supports the idea that the human SVZ contains progenitor cells and that these cells are required to migrate from the SVZ before they differentiate[22]. We were unable to detect any BrdU-immunoreactive cells in tissue from the control patient who had not received BrdU treatment, supporting the interpretation that the BrdU staining we report here reflects the persistence in the adult human brain of cell genesis.

Discussion

Our study demonstrates that cell genesis occurs in human brains and that the human brain retains the potential for self-renewal throughout life. Although earlier studies in adult primates have been unsuccessful in showing neurogenesis in the dentate gyrus[23,24], a recent report has demonstrated neurogenesis in three-year-old marmoset monkeys[6]. Although the number of BrdU-labeled cells entering the neuronal lineage seems to be lower in the human hippocampus than in marmosets, those monkeys[6] were considerably younger, even in relative terms, than the humans examined here (average age of 64.4 ± 2.9 years). Therefore, we conclude that, as in rodents[5,25], neurogenesis in the human dentate gyrus continues throughout life.

Although our results demonstrate that cells in the adult brain undergo cell division and that some of the newly generated cells can survive and differentiate into cells with morphological and phenotypic characteristics of neurons, we have not proven that these newly generated cells are functional. We also do not yet know the biological significance of cell genesis in the adult human brain. However, this does provide a basis to investigate a newly discovered type of 'neuroplasticity' in humans, one based

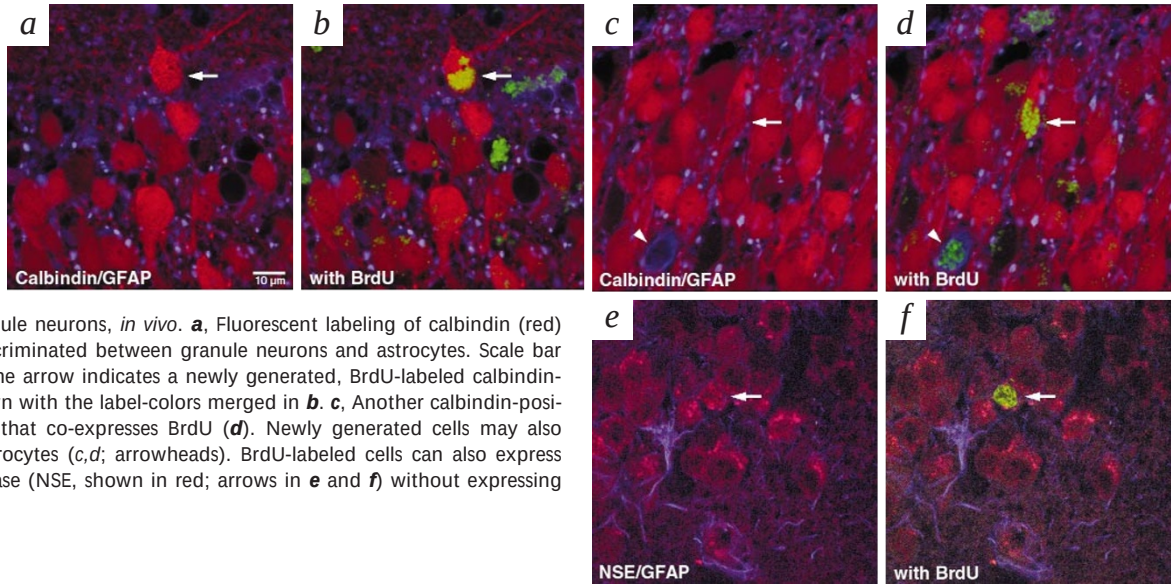

Fig. 4 Newly generated cells in the adult human dentate gyrus can express additional neuronal phenotypes. The calcium-binding protein, calbindin, is expressed by certain neuronal populations, including dentate granule neurons, *in vivo*. ***a***, Fluorescent labeling of calbindin (red) and GFAP (blue) discriminated between granule neurons and astrocytes. Scale bar represents 10 μm. The arrow indicates a newly generated, BrdU-labeled calbindin-positive neuron shown with the label-colors merged in ***b***. ***c***, Another calbindin-positive neuron (arrow) that co-expresses BrdU (***d***). Newly generated cells may also differentiate into astrocytes (*c,d*; arrowheads). BrdU-labeled cells can also express neuron specific enolase (NSE, shown in red; arrows in ***e*** and ***f***) without expressing GFAP (blue).

on addition of neurons, that has not been previously considered. Studies in rodents have shown that the adult hippocampus contains progenitor cells that can be expanded *in vitro* and grafted back into the adult brain, where they can respond to regional cues by differentiation into site-specific phenotypes, including neurons[26,27]. The presence of progenitor cells in the human dentate gyrus, reported here, indicates that these cells also may be used for *in vitro* and *in vivo* studies of cell differentiation and possibly subsequent transplantation studies. Furthermore, environmental stimulation can influence the rate of neurogenesis in the adult and senescent rodent dentate gyrus[12,17]. The potential to regulate human neurogenesis should prove to be an interesting area of investigation.

Methods

Autopsy material. Human hippocampal tissue was obtained at autopsy with the full consent of each family. All patients were diagnosed with squamous cell carcinomas at the base of the tongue, in the larynx or in the pharynx. All patients received bromodeoxyuridine (BrdU) (250 mg) dissolved in saline and given as an intravenous infusion (2.5 mg/ml, 100 ml). The BrdU was given to the patients to assess the proliferative activity of the tumor cells, expressed as BrdU-labeling index. No signs of macroscopic or microscopic metastases were found in autopsy material from the cerebrum in any of the patients. No anti-cancer therapy was administered before or during BrdU administration to any of the patients.

Tissue preparation. The hippocampal formation and ventricular zone were dissected out and post-fixed in 4% paraformaldehyde for 24 hours and then transferred into 30% sucrose solution until equilibrated. The hippocampi were sectioned (slices 40 μm in thickness) in the coronal plane on a sliding microtome and stored at –20 °C in a cryoprotecting buffer containing 25% ethylene glycol, 25% glycerin and 0.05 M phosphate buffer. For comparison, sections derived from BrdU-injected adult rats and mice that had been intracardially perfused with 4% paraformaldehyde were processed in parallel with the human tissue.

Histology. Immunohistochemical detection of BrdU requires a pre-treatment of the sections to denature DNA (ref. 5). All staining was done on free-floating sections and the blocking buffer contained both 3% normal donkey serum and 3% normal human serum (Sigma). For sections stained only for BrdU, a

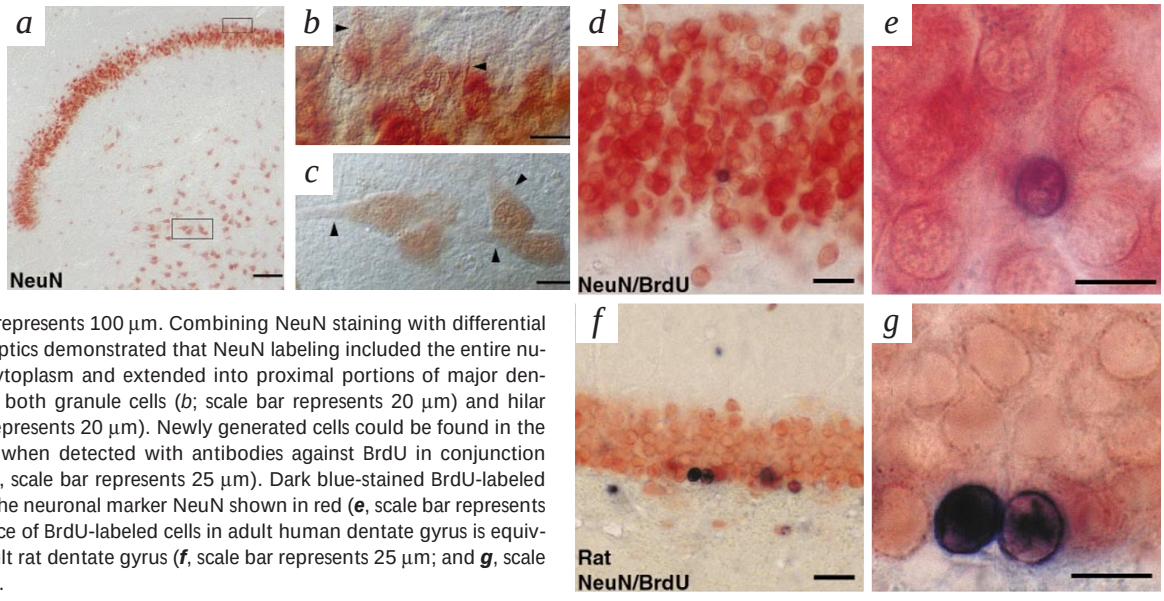

Fig. 5 Brightfield double-immunohistochemical demonstration of neuronal phenotype. ***a***, Staining with the neuronal marker NeuN labels both dentate granule cells (top inset, shown in ***b***) and hilar neurons (bottom inset, shown in ***c***). Scale bar represents 100 μm. Combining NeuN staining with differential interference contrast optics demonstrated that NeuN labeling included the entire nucleus and perikaryal cytoplasm and extended into proximal portions of major dendrites (arrowheads) in both granule cells (*b*; scale bar represents 20 μm) and hilar neurons (*c*, scale bar represents 20 μm). Newly generated cells could be found in the dentate granule layer when detected with antibodies against BrdU in conjunction with NeuN staining (***d***, scale bar represents 25 μm). Dark blue-stained BrdU-labeled nuclei can co-express the neuronal marker NeuN shown in red (***e***, scale bar represents 10 μm). The appearance of BrdU-labeled cells in adult human dentate gyrus is equivalent to that of the adult rat dentate gyrus (***f***, scale bar represents 25 μm; and ***g***, scale bar represents 10 μm.).

mouse-anti-BrdU antibody (Boehringer; diluted 1:400) was used in combination with the avidin-biotin complex method using a biotinylated donkey anti-mouse-IgG antibody (Vector Laboratories, Burlingame, California; diluted 1:167) and reacted with a diaminobenzidine (DAB) chromagen.

Immunofluorescent double- and triple-labeling was done as described[5,12]. For multiple immunostaining, BrdU was detected with a rat anti-BrdU antibody (Harlan Sera-Lab, Loughborough, England; diluted 1:500) and visualized with a FITC-conjugated secondary donkey anti-rat antibody (Jackson ImmunoResearch, West Grove, Pennsylvania; diluted 1:250). For neuronal phenotype markers, sections were incubated with one of the following antisera: rabbit anti-calbindin antiserum (SWant, Bellinzona, Switzerland; diluted 1:1,000), or mouse anti-NeuN antiserum (from R. Mullen[18]; diluted 1:20), or rabbit anti-NSE antiserum (Polysciences, Warrington, Pennsylvania; diluted 1:800). These neuronal markers were visualized by using the species-appropriate Cy3-conjugated secondary antibody (Jackson ImmunoResearch, West Grove, Pennsylvania; diluted 1:250). GFAP was detected in the same sections using a guinea pig anti-GFAP antiserum (Advanced Immunochemicals, Long Beach, California; diluted 1:250) and visualized using a Cy5-conjugated donkey anti-guinea pig antibody (Jackson ImmunoResearch, West Grove, Pennsylvania; diluted1:250).

For double immunostaining using brightfield chromagens, sections were incubated with a pooled solution of rat anti-BrdU (Harlan Sera-Lab, Loughborough, England; diluted 1:500) and mouse anti-NeuN (from R. Mullen[18]; diluted 1:100) antisera. After being rinsed and blocked, sections were incubated first with a biotinylated donkey anti-rat antibody (Jackson ImmunoResearch, West Grove, Pennsylvania; diluted 1:250), followed by incubation with an alkaline phosphatase avidin–biotin substrate and then reaction with the blue chromagen (Vector Blue; Vector Laboratories, Burlingame, California). After being rinsed and blocked further, the sections then were incubated with a biotinylated donkey anti-mouse antibody (Jackson ImmunoResearch, West Grove, Pennsylvania; diluted 1:250) followed by incubation with a peroxidase avidin-biotin substrate and then reaction with the red chromagen (3-amino-9-ethylcarbazole or AEC; Vector Laboratories, Burlingame, California). Sections were mounted and coverslipped with an aqueous mounting medium.

Fluorescent signals were imaged using a confocal laser scanning microscope equipped with a krypton/argon mixed gas laser (Bio-Rad MRC1024; Bio-Rad, Richmond, California) using individual collection of wavelengths to minimize artifactual detection of non-specific fluorescent emission. At least 20 BrdU-positive cells within multiple immunofluorescently stained sections from each patient were examined on the confocal microscope to determine the phenotype of BrdU-labeled cells. Brightfield images were derived from conventional photomicrographs digitized by using a slide scanner. Figures were composed by using Adobe Photoshop (Adobe Systems, Mountain View, California) with image adjustments confined to creating an equivalent signal distribution between panels.

Quantitation. The numbers of BrdU-positive cells in the granule cell layer, the subgranular layer and the hilus, and their corresponding sample volumes were determined in five to seven immunoperoxidase-stained coronal sections 40 μm in thickness, at least 240 μm apart, from each patient. Area estimations were done on an IBAS image analysis system. The section thickness of 40 μm (microtome setting) was used in the dissector estimation of volume. The number of BrdU-positive cells was counted within the granule cell layer (GCL) and two cell diameters below the granule cell layer, ignoring the cells in the uppermost focal plane and focusing through the thickness of the section (optical disector principle; refs. 14,15,16) to avoid oversampling errors. The subgranular zone (SGZ) was defined as the area from one cell diameter within the GCL from the hilus-GCL border and two cell diameters below the hilus-GCL border (Fig. 1). Quantitative analysis of BrdU immunoperoxidase-stained sections was done on a Nikon microscope equipped with a video camera. The results are expressed as BrdU-positive cells per sample volume per section.

SUMMARY

Dopamine is crucial for habit learning. Activities of midbrain dopaminergic neurons are regulated by the cortical and subcortical signals among which glutamatergic afferents provide excitatory inputs. Cognitive implications of glutamatergic afferents in regulating and engaging dopamine signals during habit learning, however, remain unclear. Here, we show that mice with dopaminergic neuron-specific NMDAR1 deletion are impaired in a variety of habit-learning tasks, while normal in some other dopamine-modulated functions such as locomotor activities, goal-directed learning, and spatial reference memories. In vivo neural recording revealed that dopaminergic neurons in these mutant mice could still develop the cue-reward association responses; however, their conditioned response robustness was drastically blunted. Our results suggest that integration of glutamatergic inputs to DA neurons by NMDA receptors, likely by regulating associative activity patterns, is a crucial part of the cellular mechanism underpinning habit learning.

INTRODUCTION

Many acts, after repetitive practice, would transform from being goal-directed to automated habits, which can be carried out efficiently and subconsciously. Habits help to free up the cognitive loads on routine procedures and allow us to focus on new situations and tasks. Despite breakthroughs unveiling participation of different anatomical structures in habit formation (Knowlton et al., 1996; Yin and Knowlton, 2006), the underpinning physiological mechanisms and how different network circuitries integrate relevant information remain unclear.

Dopamine (DA) is an important regulator of synaptic plasticity, especially in the basal ganglia, a structure essential for habit learning. In both human patients (Fama et al., 2000; Knowlton et al., 1996) and rodents (Faure et al., 2005), habit learning is often found impaired following dopaminergic neuron degeneration. Dopamine has thus been postulated as a main modulator in the mechanisms subserving habit learning (Ashby et al., 2010). Despite this importance, the mechanisms modulating dopamine during habit learning have yet to be fully investigated. Studies have shown that habit-learning deficits caused by dopamine deafferentation could not be rescued by simple intrastriatal injections of DA agonists (Faure et al., 2010). These observations suggested that dopamine, the modulator itself, might need to be regulated during normal habit learning. Anatomically, along with cholinergic inputs, glutamatergic afferents from brain structures such as pedunculopontine tegmental nucleus (PPTg), subthalamic nucleus (STN), and prefrontal cortex (PFC) provide main forms of excitatory inputs to the midbrain DA neurons (Grace et al., 2007). NMDA receptors (NMDARs), members of the ionotropic glutamate receptor family, are important regulators of DA neuron activity. First, synaptic plasticity in the glutamatergic afferents to DA neurons depends on NMDARs (Bonci and Malenka, 1999; Overton et al., 1999; Ungless et al., 2001). This plasticity can be modulated by experiences, environmental factors, and psychostimulant drugs (Bonci and Malenka, 1999; Kauer and Malenka, 2007; Saal et al., 2003). Second, iontophoretic administration of NMDAR antagonists, but not AMPAR-selective antagonists, attenuated phasic firing of DA neurons, an activity linked to reward/incentive salience (Schultz, 1998), without changing the frequency of tonic firing (Overton and Clark, 1992). Third, in drug addiction studies, NMDARs in DA neurons are essential for developing nicotine-conditioned place preference (Wang et al., 2010) and likely also involved in cocaine-conditioned place preference (Engblom et al., 2008; Zweifel et al., 2008). Thus, we postulated that modulation of DA neurons by NMDARs might be important in engaging DA neurons in the habit learning. Here, we set out to examine the roles of NMDARs in DA neurons, by generating DA neuron-specific NR1 knockout mice and testing them in a variety of habit-learning paradigms (Devan and White, 1999; Dickinson et al., 1983; Packard et al., 1989; Packard and McGaugh, 1996). In order to understand the cellular mechanisms, we also recorded the DA neurons in these mice using multielectrode in vivo neural-recording techniques (Wang and Tsien, 2011).

RESULTS

Production and Basic Characterization of DA Neuron-Selective NR1 Knockout Mice

These mice, named "DA-NR1-KO," were produced by crossing floxed NR1 (fNR1) mice (Tsien et al., 1996) with *Slc6a3+/Cre*

(C) Immunofluorescent staining of DAT-Cre/Rosa-Stop-lacZ mouse brain with lacZ antibody, with anti-TH antibody and overlay of the two stainings.

(D) Immunofluorescent staining of DA-NR1-KO and wild-type control brain with anti-NR1 antibody, anti-TH antibodies and overlay of both stainings. Arrowheads indicate position of some TH-positive neurons. TH signals colocalize with NR1 in the control brain, but not in the DA-NR1-KO brains. Pictures in the larger boxes are the 3-fold enlargement of the pictures shown in the respective small boxes.

transgenic mice that express Cre recombinase under DA transporter promoter (Zhuang et al., 2005) (Figures 1A and 1B). The DA neuron-specific deletion of the NR1 gene was confirmed by both the reporter gene method (Figure 1C) and immunohistochemistry (Figure 1D), which showed that the gene deletion was restricted to the dopaminergic neurons in regions such as the VTA and the substantia nigra. No obvious changes were observed in the expression pattern of tyrosine hydroxylase (TH), the catecholamine neuronal marker, suggesting that there was no obvious loss of dopaminergic neurons (see Figure S1 available online).

DA-NR1-KO mice were born in the expected Mendelian ratios and visually indistinguishable from the controls. Additionally, they were normal in locomotor activities in a novel open field (Figure 2A), in learning the rotarod tests (Figure 2B), in an anxiety test using the elevated plus maze (Figure 2C), and in the novel object recognition tests (Figure 2D). These results showed that many of the behavioral functions that were sensitive to dopamine dysfunctions were preserved in the DA-NR1-KO mice.

DA Neurons in the DA-NR1-KO Showed Normal Tonic Firing, Reduced Phasic Firing, and Reduced Responses to the Reward-Predicting Cue

In order to investigate the impact of NR1 deletion on the cellular properties of DA neurons, we recorded the activities of these neurons in both the DA-NR1-KO mice and wild-type control littermates. Movable bundles of 8 tetrodes (32 channels) were implanted into the ventral midbrain, primarily the VTA. The putative DA neurons were identified based on their firing patterns and their sensitivity to dopamine receptor agonist apomorphine (1 mg/kg, i.p.) at the end of each recording session (Figures 3A–3D).

A total of 14 putative DA neurons from 4 mutant mice and 16 from 6 wild-type controls were recorded and analyzed. Phasic-firing activities or bursting was defined as a spike train beginning with an interspike interval (ISI) smaller than 80 ms and terminating with an ISI greater than 160 ms. Compared with the control neurons, phasic-firing activities were greatly reduced in the DA-NR1-KO neurons. The observed median frequency of phasic firing decreased from 0.78 ± 0.09 Hz in the control DA neurons to 0.36 ± 0.09 Hz in KO DA neurons. (Mann-Whitney U test, $p < 0.01$) (Figure 3E). A significant reduction was also observed in the percentages of spikes fired in phasic activities (34.7% in the controls versus 21.2% in the DA-NR1-KO; Mann-Whitney U test, $p < 0.01$) (Figure 3F). The total firing rate was also reduced in the mutant DA neurons. This appeared to be correlated with reduced burst set rate (5.18 ± 0.59 Hz, control, versus 3.85 ± 0.38 Hz, KO; $r = 0.7719$, Mann-Whitney U test, $p < 0.01$) (Figure 3G). No significant difference was observed in the tonic firing between the mutant and control groups. (4.42 ± 0.44 Hz in control, versus 3.29 ± 0.36 Hz in KO; Mann-Whitney U test, $p > 0.05$) (Figure 3H).

To further evaluate the response of DA neurons in a learning task, mice were trained 40 trials per day in a Pavlovian-conditioning paradigm in which a 5 KHz tone that lasted 1 s proceeded immediately before the delivery of a food pellet. DA neurons from both genotypes were able to associate the tone with phasic firing, but the conditioned responses were much weaker in the DA-NR1-KO group (Figure 4A). Although DA-NR1-KO neurons showed increased firing over the days during the training, their responses were significantly reduced compared with the controls on day 1 (19.21 ± 3.24 Hz, control, versus 9.74 ± 0.30 Hz, KO; $p < 0.01$), day 2 (36.33 ± 4.39 Hz, control, versus 16.43 ± 4.01 Hz, KO; $p < 0.01$), and day 3 (59.38 ± 3.82 Hz, control, versus 33.88 ± 4.30 Hz, KO; $p < 0.01$) (Figure 4B). These data suggested that while NMDAR1 deletion did not completely prevent DA neurons from developing conditioned responses (bursting) toward reward-predicting cues, it did, however, greatly lower the robustness of the bursting response, a phenomena that we call DA neuron blunting.

Habit Learning, but Not Goal-Directed Learning, Was Impaired in the Operant Appetitive Conditioning

To assess habit learning, we first tested the mice in a lever-pressing operant-conditioning task. In this task an instrumental

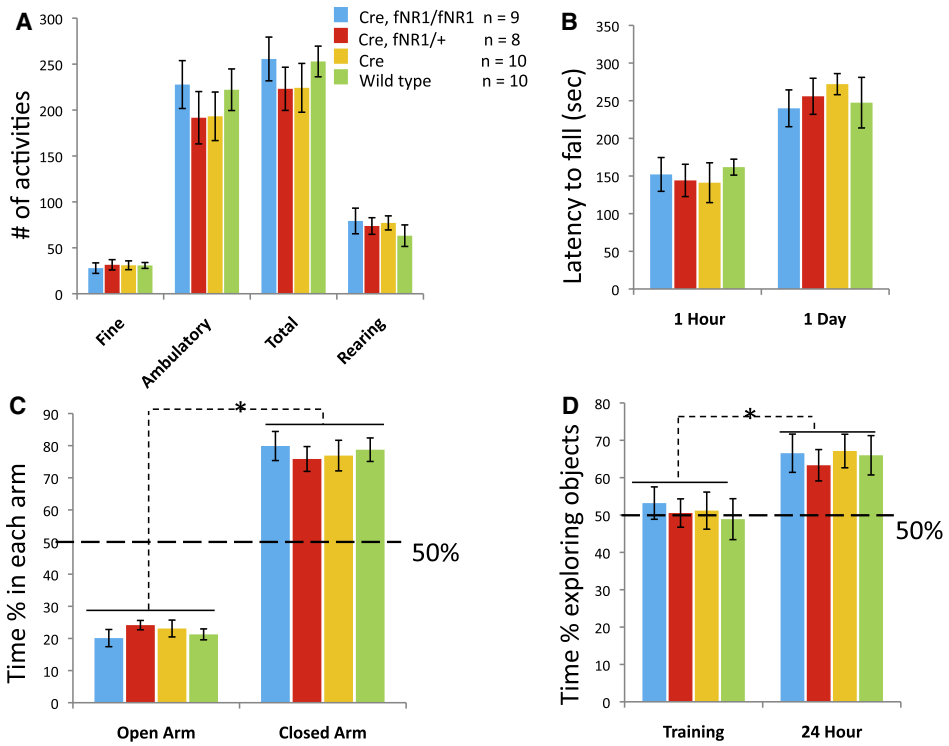

Figure 2. Basic Behavioral Characterization of DA-NR-KO Mice

(A) Locomotor activity tests in a novel environment. Fine movements, ambulatory movements, total movements (total of fine plus ambulatory movements), and rearing were scored. Post hoc comparisons revealed no differences among the mutant and the three control groups.

(B) Rotarod test. Mice were tested 1 and 24 hr after initial training. All mice performed better (as shown by extended latencies) at 24 hr. Post hoc comparisons showed no differences among the mutant and control groups at either time points.

(C) Anxiety level tested using elevated plus maze. Percentages of time spent in each arms were calculated. Post hoc comparisons showed no differences among the genotypes. *$p < 0.05$, Student's t test.

(D) Novel object recognition test. At "24 hour," Time % = time spent exploring novel object/(time spent exploring familiar object + time spent exploring novel object). At "Training," Time % = time spent exploring one object/total time spent exploring both objects. All mice spent more time on the novel object at 24th hr ($p < 0.01$), with post hoc comparisons revealing no differences among the groups tested. Error bars represent SEM. *$p < 0.05$, Student's t test.

action, pressing lever to obtain food, can transform from a goal-directed to a habitual response after extensive training and become progressively less sensitive to devaluation of outcome (Dickinson et al., 1983). The decreased sensitivity can thus be measured as a behavioral readout of habit learning (Figure 5A). Both mutant and control mice learned to press the lever on an extensive training protocol consisting of 4 days of continuous reinforcement (CRF), 2 days of random interval (RI) 30 s, and 6 days of RI 60 s schedules (Dickinson et al., 1983). Mice in both groups increased lever-press rates during the training (CRF days 1–4, RI 30 s days 5 and 6, RI 60 s days 7–12) (Figure 5B). A two-way ANOVA of repeated measures, with days and genotype as factors, showed no effect of genotype ($F_{(1, 231)} = 0.07$), a main effect of days ($F_{(11, 231)} = 51.4$; $p < 0.01$), and no interaction between these factors ($F_{(11, 231)} = 0.269$). This result suggested that the DA-NR1-KO mice have normal wanting of the pellet reward and exhibited normal goal-directed learning.

Lever pressing was then tested after the outcome devaluation. Mice were prefed with either regular mouse chow to which they had been exposed in their regular home cages (nondevalued condition/control), or purified high-energy pellets that are identical to the rewards earned during lever-press sessions (devalued condition). Feeding with mouse chow was used as a control for the overall level of satiety, causing little reduction in the rewarding value of the purified high-energy pellets. Levers were inserted in the 5 min long probe test that immediately followed the 1 hr unlimited food exposure (pellets or chow). No pellets were given during the tests. Comparing numbers of lever press during the tests showed that, while no differences were found between the mutant and the control mice on nondevalued condition ($p = 0.94$) or between the devalued and nondevalued conditions ($p = 0.153$) in the control group, there was a significant difference in the mutant mice between devalued and nondevalued conditions ($p < 0.01$). Furthermore, there was also a significant difference between the mutant and control mice on devalued condition ($p < 0.05$). A two-way ANOVA of repeated measures, with treatment and genotype as factors, showed an interaction between the two factors ($F_{(1, 21)} = 4.98$; $p < 0.05$) (Figure 5C). These suggested that the conditional knockout mice failed to develop the lever-pressing habit despite extensive training, and their action stayed goal directed.

Spatial Navigation Habit, but Not Spatial Memory, Was Impaired in the Positively Reinforced Plus Maze

Habit learning was then assessed in a navigation-based paradigm using plus maze place/response-learning tasks (Devan and White, 1999; Packard, 1999; Packard and McGaugh, 1996). Littermates in genotypes *Slc6a3+/Cre; fNR1/+*, *Slc6a3+/Cre*, and wild-type served as three control groups for the DA-NR1-KO mice. The maze was built with transparent walls and placed in a room furnished with spatial cues. The schematic training and testing schedules are shown in Figure 6A. Naive animals, always starting from the same location in the maze (the "south" arm), were trained to find a fixed target site (in the "east" arm) (Training I in Figure 6A). In order to facilitate developing habit-based navigation, the north and the west arms were both closed. It has been shown that under this paradigm, normal mice would learn to search the target using spatial reference memory after moderate training but would switch to habitual navigation after extensive training (Packard and McGaugh, 1996). Probe trials, during which the start location switched from the "south" arm to the "north" arm, were given at different time points to allow dissociation of the spatial and habitual strategies. Thus, mice using the "habit strategy" were predicted to turn right (into the "west" arm), whereas the "spatial" mice, guided by distal spatial cues, were predicted to go to the "east" arm, where the target resided during training.

All mice were trained in ten trials per day for 5 consecutive days before the first probe trial on day 6 (Probe 1 in Figure 6A). During this probe trial the DA-NR1-KO group and control mice showed similar preferences (χ^2 [3, n = 43] = 0.346; p = 0.951) for the "spatial" strategy, opting to turn left toward the "east" arm (Figure 6B), suggesting that they had similarly acquired the spatial memory and that they shared comparable motivation. All mice were then trained for 10 additional days before the second probe trial (Probe 2 in Figure 6A) on day 17. During this probe trial no significant differences were found among the three control groups (χ^2 [2, n = 29] = 0.499; p = 0.779). As a group, control mice opted to "turn right" (and into the "west" arm) significantly more on day 17 than on day 6 (χ^2 [1, n = 29] = 22.587; p = 0.00000201), indicating a learned "habit"-based searching strategy. In contrast, less than 10% of the DA-NR1-KO mice (compared with 80% of control mice) (mutants versus controls: χ^2 = 7.244; p = 0.007)

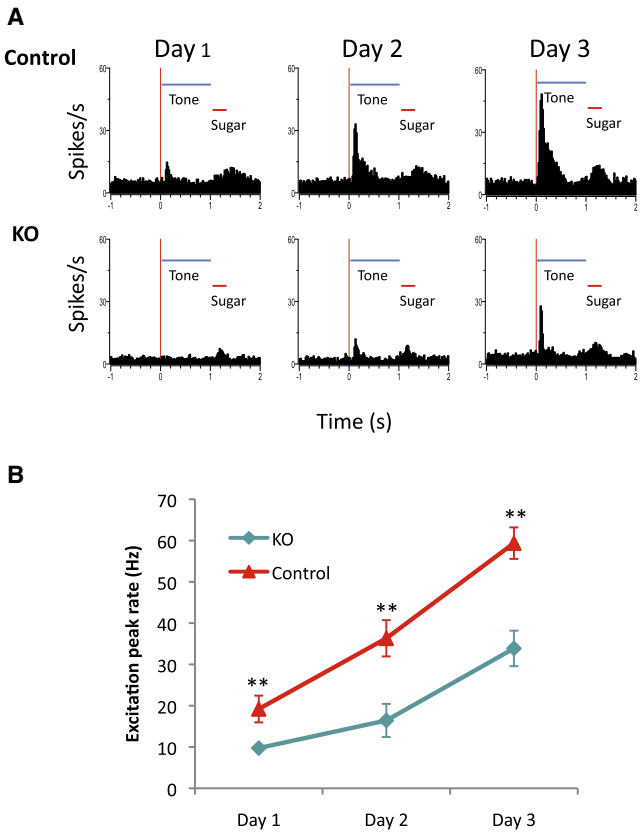

Figure 4. Responses of Putative Dopamine Neurons in 3 Day Reward Test

(B) Lever-pressing speed during training days. No significant difference was discovered at any day of the training between the mutant and control groups.

(C) Lever pressing in the 5 min extinction test after devaluation of outcome and nondevaluation of outcome. Mutant mice showed significantly reduced lever pressing at the devalued condition versus both control mice at devalued condition and mutants at nondevalued condition. No significant reduction was detected for the control mice between the devalued and nondevalued conditions. (See text for all the statistics.) Error bars represent SEM. *p < 0.01, lever presses by the DA-NR1-KO mice during nondevalued versus devalued tests; **p < 0.05, lever presses during devalued test by DA-NR1-KO versus by control.

opted to turn "right" on day 17 (Figure 6B), suggesting that they failed to learn the "habit"-based strategies and, instead, kept using the "spatial" strategy.

To confirm that the deficits in the plus maze tasks were indeed from habit learning, right after the second probe trial, mice were further challenged in a "relearn after 90° rotation" procedure (Training II, Figure 6A), three trials a day for 2 days within the exact same maze and surrounding cues. During the training, both the west and south arms were blocked. The start box was placed in the "east" arm, and the food rewards were in the "north" arm. Mice were tested in a rotation test on day 19, and accuracies to locate the food were scored. Mice started from the "east" arm with all arms open during the test (Figure 6A). For "habit" mice who had learned to "turn right" during previous training sessions (days 1–16), this new learning was simply a retraining, in which the same habit response (turning "right") would lead them to the new food location. However, for the "spatial" mice, switching of target location from the "east" arm to the "north" arm conflicted with the previously learned spatial relationship and, thus, was predicted to inhibit new learning. As in Figure 6C, the mutants showed significantly less success (turning "right" or into the "north" arm) (χ^2 [3, n = 42] = 11.667; p = 0.0006), whereas no difference was found (χ^2 [3, n = 42] = 0.73; p = 0.694) among the three control groups. This supported the notion that mutant mice failed to learn the habit strategy, even after the extensive training.

Spatial Navigational Habit Learning, but Not Spatial Memory, Was Impaired in the Negatively Reinforced Plus Maze

Because many studies suggested that dopamine is important for reward pathways, we asked whether habit-learning deficits seen in the DA-NR1-KO mice hinged on the nature of the reinforcement. The aforementioned experiments were replicated in a water-based plus maze, in which the sole escape from the water was for mice to locate and climb onto a hidden platform in the end of one arm. This water-based plus maze behavior was driven by the desire to escape from the negative environment and offered an additional opportunity to compare with habit learning based on positive reinforcement such as the seeking of a food reward. All parameters such as maze dimensions, cues used, starting and target locations, number of trials per day, and numbers of days in training remained the same as those in the previous food-rewarded experiments (Figure 6A).

The first probe trial revealed no significant differences between any two of the four genotypes (χ^2 [3, n = 43] = 0.346; p = 0.951). The second probe trial showed that over 80% of the control mice had adopted the "habit" strategy, whereas the mutant mice remained strongly "spatial" (Figure 6D). No differences were found among the three control groups (χ^2 [2, n = 29] = 0.499; p = 0.779). As a group, the control mice opted for the "habit" strategy significantly more on day 17 than on day 6 (χ^2 [1, n = 29] = 22.587; p = 0.00000201). A significantly lower percentage of DA-NR1-KO mice opted to "turn right" (7.14% versus 80% in the control mice; χ^2 [1, n = 43] = 20.904; p = 0.00000483). The deficits in habit learning were further confirmed in the rotation test given after 2 days of the "relearn after 90° rotation" challenge task (Training II, Figure 6A). A significantly smaller proportion of the mutant mice (28.6%) in contrast to 80% of the controls were able to successfully locate the new platform position (one-tailed probability = 0.000388, Fisher's exact test). These data thus agreed with the findings from the above food-rewarded tasks suggesting that the learning deficits were unlikely contingent on the types of reinforcement employed in the training process.

Due to the significant involvement of spatial learning in the plus maze task, mice were tested in a spatial version of the plus maze (Figure 7A). They were trained six trials per day for 6 days to find a hidden platform in the water-filled plus maze. With all four arms open, starting points switched between trials in each day rotating among the distal ends of three arms that did not contain the platform, following a semi-random order. The platform location remained fixed throughout. A probe test was given on day 10, 3 days after the training session ended. During the test, with the platform removed, mice were released to the center of the maze and allowed to search for 60 s. Durations spent by each mouse in each arm were recorded (Figure 7B). Mice from all four groups spent significantly more time searching in the target arm (mutants, $F(3,32) = 101.292$, $p < 0.001$; Cre, fNR1/+, $F(3,28) = 134.996$, $p < 0.001$; Cre, $F(3,36) = 147.806$, $p < 0.001$; wild-type, $F(3, 36) = 294.358$, $p < 0.001$; Newman-Keuls post

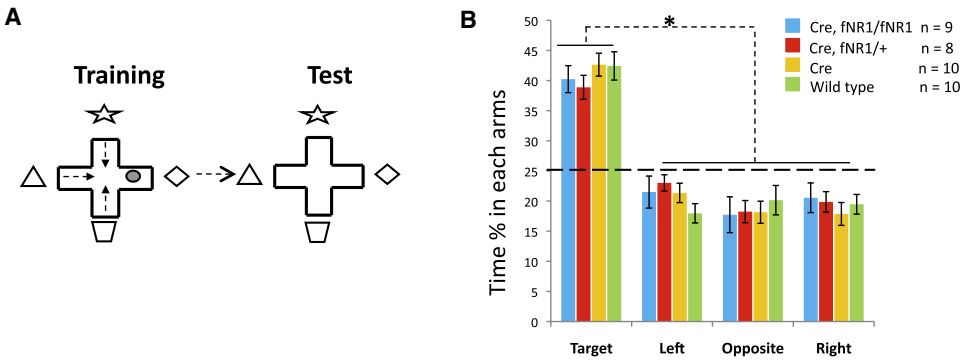

Figure 7. Spatial Memory Test Using Plus Maze

(B) Probe trial test. All mice spent more time searching in the target arm. No difference was detected between the mutant and control groups. *$p < 0.01$, time spent in the target arm versus in the other three arms. Error bars represent SEM. (See text for all the statistics.)

hoc comparison [the target arm compared to all the other arms], $p < 0.01$ for all genotypes). No differences were found between the mutant and any control groups, suggesting that spatial learning abilities were unlikely a factor causing the habit-learning deficits observed in the DA-NR1-KO mice.

Habit Learning in a Nonspatial Zigzag Maze-Based Habit Task Was Impaired

Instead of compromising habit learning per se, DA-specific NR1 deletion could have skewed the competition between "spatial" and "habit" memory systems in the plus maze task. In order to investigate this possibility, we designed a nonspatial "zigzag maze" task as a more direct measurement of habit learning. As shown in Figure 8A, the water-filled zigzag maze consisted of eight arms similar in length. Mice were trained to escape onto a hidden platform. Six different starting points were chosen, each paired with its own location of the hidden platform. The platform locations were chosen so that they would be reached after two consecutive right turns from the start point. All mice were trained 12 trials per day for 10 days. To facilitate developing the turning habits, some arms were blocked (red lines) so that mice were only allowed the correct turn at each intersection. A probe test was given on day 11 in which mice were placed at a random start location. Some arms in the maze remained blocked (red lines), but unlike in training, mice were allowed to choose between turning "left" or "right" at two intersections (Figure 8A). Mice were scored for whether they finished the two consecutive right turns (counted as "successful"). No differences were found among the three control genotypes (all between 90% and 100%, χ^2 [2, n = 29] = 1.968; p = 0.374) (Figure 8B), and they were pooled. The conditional knockout mice showed a significantly lower successful rate in making the two consecutive right turns (one-tailed probability = 0.000196, Fisher's exact test), again suggesting that the DA-NR1-KO mice are defective in developing the navigation habit.

DISCUSSION

Here, we studied mutant mice with DA neuron-selective NR1 deletion using a set of behavioral tasks as well as in vivo neural-recording techniques. Behavioral analysis revealed that the DA-NR1-KO mice were impaired in several forms of habit learning. In an operant task where both the mutant and control mice learned a goal-directed action in the initial training, extensive training shifted, but only in the control mice, the learned action from goal directed to habitual. In the mutant mice, this action remained goal directed and, thus, sensitive to reward devaluation. Similarly, in plus maze tasks, whereas both mutants and the controls learned to navigate based on spatial cues in initial training, extensive training shifted navigation from spatial into habitual also only in the controls, while the mutants' navigation remained spatially oriented. Such deficits in habit learning were observed in both positively reinforced and negatively reinforced tasks. This is consistent with our recent recordings showing that DA neurons employ a convergent encoding strategy for processing both positive and negative values (Wang and Tsien, 2011). One notable finding of those in vivo recording experiments was that some DA neurons exhibit a stimulus-suppression-then-rebound-excitation type firing pattern in response to negative experiences (Wang and Tsien, 2011). This offset-rebound excitation may encode information reflecting not only a relief at the termination of such fearful events but, perhaps, provide some sort of motivational signals (e.g., motivation to escape).

Therefore, our data strongly suggested that NMDAR functions in DA neuron be essential for habit learning. A previous study by Zweifel et al. (2009) reported that the DA neuronal-selective NR1 KO mice were impaired in learning a water maze task and also impaired in learning a conditioned response in an appetitive T maze task, seemingly in disagreement with our results of normal spatial learning and goal-directed learning. The experimental conditions used in their studies were, however, quite different from those in ours. The water maze deficit was transient and detectable only during the very early part (day 2 in a 5 day session) of their training sessions. The T maze was a goal-directed paradigm that likely also involved mice learning context association between landmarks and rewards. Additionally, the action-reward contingency was also different than that in the operant paradigm that we used. It is very likely that factors such as task difficulties, amount of training, cue saliencies, temporal and spatial contingencies between the CS, and the

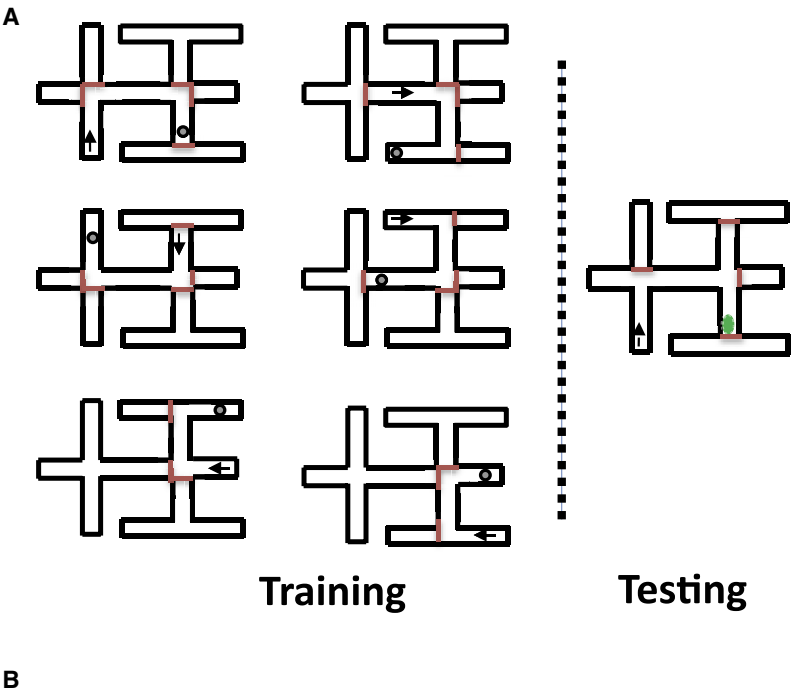

Figure 8. Habit-Learning Test Using Zigzag Maze

rewards can affect the type and amount of involvement by DA neurons. Using in vivo neural recordings, we observed that although the response to cue-reward association is much attenuated in DA-NR1-KO neurons in term of both response peak amplitude and duration, these DA neurons, nonetheless, still could form the cue-reward association. Interaction between the blunted responsiveness of DA and test conditions may leave some goal-directed learning impaired by the NR1 deletion, whereas spare some others. A good example is that in a report published later by the same group, the authors reported that the NR1 KO mice were normal in a goal-directed learning paradigm (Parker et al., 2010). In our study the test conditions and amount of trainings we used allowed the controls as well as the mutants to learn goal-directed and spatial learning normally and indistinguishably. After extensive training under these conditions, the mutant mice could not develop the habit learning, whereas the controls clearly did.

Dopamine is an important modulator for the habit learning (Wickens et al., 2007; Yin and Knowlton, 2006). Most of the current understanding of its involvement in the habit learning has so far centered on the downstream pathways and structures such as the dorsal striatum and more recently the PFC (Wickens et al., 2007; Yin and Knowlton, 2006). Our finding here highlighted the importance of glutamatergic modulations of the DA neuron circuitry itself, in this case mediated by NMDARs, and suggested that this upstream pathway should be considered an integral part of the habit-learning networks. With perception of the environmental stimuli likely carried out by glutamatergic signals, it is conceivable that NMDARs in dopaminergic neurons participate in the controlling and fine-tuning of dopaminergic neuron activity patterns during habit formation. An important part of this regulation is perhaps to create the cue-reinforcement association at an appropriate level in terms of response robustness and overall DA neuron network patterns so that DA neurons would respond accordingly to procedures and cues with higher incentive salience. NMDARs are required in mediating synaptic plasticity in glutamatergic synapses onto DA neurons (Bonci and Malenka, 1999). Our results showed that modulation by NMDARs facilitates bursting of DA neurons toward the learned reward-predicting cues. It is conceivable that the function of NMDARs in regulating phasic firing may be closely linked to its roles in regulating synaptic plasticity. In fact, studies have shown that enhanced synaptic strength onto dopamine neurons may act to facilitate their phasic firing (Stuber et al., 2008).

The blunting of the phasic firing of DA neuron in the mutant mice can contribute or even result in the habit-learning deficits. There are several brain regions involved in habit learning that can be affected by this blunting. The most intuitive one is the striatum. Dopamine signaling has been postulated as the mechanism that trains the striatum, which in turn trains the cortex to establish the appropriate sensorimotor associations required for developing habits (Ashby et al., 2010; Wickens et al., 2007).

Dopamine modulates the plasticity in the corticostriatal synapses, facilitating induction of LTP in conditions that would otherwise induce LTD. This facilitation requires dopamine D1 receptor (Calabresi et al., 2000). The low affinity of D1 receptors toward dopamine coupled with the fast dopamine reuptake (Cragg et al., 1997) in the striatum likely makes the dopamine modulation sensitive to the blunting of phasic release. From a network point of view, it has been reported that dopamine can cause changes in the coordinated activity of neuronal ensembles in corticostriatal circuits and by doing so "gate" the inputs in those downstream regions (Costa et al., 2006). Thus, when dopamine level is low, such as when bursting activities are insufficient, it fails to produce and reinforce these networks' connectivity underlying habit formation. Other than the striatum, reduced bursting of DA neurons may also affect activities of structures such as the PFC of which lesion of the medial infralimbic area was reported to impair expression of a learned habit (Coutureau and Killcross, 2003). Studies have shown that tonic dopamine concentration in the prefrontal area, likely due to the relatively slower dopamine reuptake (Seamans and Yang, 2004), may be affected by previous phasic dopamine release (Matsuda et al., 2006). The presence of background dopamine signal converts LTD to potentiation. This "priming" requires time to develop and requires D1 and D2 receptors, both of which have low affinity to dopamine. It is very likely that this phasic release-induced "priming" could also be affected by the amount of DA neurons bursting, thus, by blunting of DA response. It will be of great interest to dissect the various roles of those different brain regions in habit formation in future studies.

It is also important for future research to further analyze the contributions of NMDARs within different dopamine subpopulations, and temporally within different phases of habit learning. The potential subregional circuitry within the DA neuron populations in the VTA and SNr regions can be highly crucial for integrating distinct cortical and subcortical inputs (Grace et al., 2007; Lammel et al., 2011; Lisman and Grace, 2005). Thus, it is conceivable that additional subregional-specific manipulations and analyses could further elucidate how the glutamatergic regulation of DA neurons, as revealed by our current study, modulates habit formation.

In summary our study has provided several important insights about NMDAR in DA neurons and habit learning. First, NMDARs in DA neurons are required for learning habits, including appetitive lever pressing and spatial navigational habits. Second, the dependence of habit learning on NMDARs in DA neurons was observed in both positively and negatively reinforced trainings. Third, DA neurons lacking the NMDARs can still form the cue-reward association but with greatly reduced phasic activity as well as conditioned response robustness. Taken together, our results suggest that the NMDARs in DA neurons are an important modulator of DA neurons' response robustness in cue-reward association and an essential element underpinning habit learning.

EXPERIMENTAL PROCEDURES

Subjects

Mice carrying alleles of *NMDAR1* flanked by loxP sites (*fNR1*) were bred with Slc63a Cre transgenic mice. Offspring were genotyped by PCR for both the Cre transgene and for the floxed *NMDAR1* (*fNR1*) locus. Mice used in these experiments have been bred for at least five generations onto the C57/BL6 background. Animals were maintained on a 12 hr light/dark cycle in the Georgia Health Sciences University animal care facility. Except for when specified in experiment, such as when food pellets were used as rewards, food and water were given ad libitum. All procedures relating to animal care and treatment conform to the Institutional and NIH guidelines. For behavioral tests in the study, we used male mice around 1 year old in age. These animals have been prescreened to make sure that they have normal vision and hearing capacity.

Immunohistochemistry

Mice were perfused transcardially with 4% paraformaldehyde (PFA) in 1× PBS followed by a postfixation in 4% PFA overnight. Coronal sections (50 μm thick) were cut on a vibratome and collected in 0.5% PFA in 1× PBS and stored at 4°C before use. For double-immunofluorescent staining of β-galactosidase and TH, sections were incubated at 4°C overnight with gentle shaking in primary antibody (anti-β-galactosidase [pAb] 1/5,000, Invitrogen; anti-TH [monoclonal antibody] 1/1,000) in a buffer containing 0.05% Tween 20, 10% normal goat serum, and 1× PBS following preincubation in 10% normal goat serum and 1× PBS at room temperature for 2 hr. The sections were then incubated with Alexa-conjugated secondary antibodies (1/200; Invitrogen) at room temperature for 2 hr. β-Galactosidase IR was visualized by Alexa 568 and TH IR by Alexa 488. A similar procedure was employed to double stain NMDAR1 and TH except that anti-NR1 (polyclonal antibody 1:100; Chemicon, Temecula, CA, USA) was used as the primary antibody for NMDAR1. The sections were incubated with Alexa-conjugated secondary antibodies (1/200; Invitrogen) at room temperature for 2 hr. NMDAR1 was visualized by Alexa 488 and TH IR by Alexa 594. Fluorescent images were captured with a confocal laser-scanning microscope and an epifluorescence microscope.

Elevated Plus Maze

This apparatus consists of a center platform (5 × 5 cm) 37 cm off the ground with four branching arms (30 cm long and 5 cm wide). Two of the four arms are open, and the other two arms are enclosed by black walls (20 cm high). Testing was performed during light phase in a dimly lit room (50 lux). Animals were placed on the center platform and scored for arm entries and time spent in each arm. Percentages of time animals spent in the open arms were calculated as the final readout of anxiety. Unpaired t tests were used to compare the significance between the different genotypes.

Rotarod

RotaRod analysis was performed using the mouse version of ROTA-ROD manufactured by San Diego Instruments (San Diego, CA, USA). Mice were trained by allowing them to run on a rotarod rotating at 30 rpm for a total time span of 5 min. (Time counting was stopped when mice dropped until they were put back onto the rotarod again.) During the tests mice were again placed on top of the rotarod, which rotated at 30 rpm. Durations of each mouse that stayed on the rotarod (latency to fall) were recorded. Any mice remaining on the apparatus 300 s after the starts were removed, and the time was scored as 300 s. Unpaired t tests were used to compare the significance between the latencies in different genotypes.

Open-Field Activity Test

Locomotor activity was measured by scoring beam breaks in activity chambers (San Diego Instruments). Prior to open-field tests, animals were handled for 2 consecutive days. Standard rat cages were used as the novel open field for the mice tested. Locomotor activities were recorded for 1 hr and scored for both 5 min and 1 hr. Unpaired t tests were used to compare the significance in fine movements, ambulatory movements, and rearing between the different genotypes.

Instrumental Training

Mice were placed on a food-deprivation schedule to reduce their weight to 80%–85% of their baseline weight. They were fed for 2 hr with mouse chow

in their home cages each day after training. Water was available at all times in the home cages.

Training and testing took place in eight Med Associates operant chambers (21.6 cm length × 17.8 cm width × 12.7 cm height) housed in boxes with sound-attenuating walls. Each chamber was equipped with a food magazine, two retractable levers, one on each side of the magazine, and a 3 W, 24V house light mounted on the same wall, but above the food magazine. Bio-Serv 20 mg pellets from a dispenser into the magazine were used as reward. The software Med-PC-IV from Med Associates was used for equipment control and behavior recording.

Lever-Press Training

At the beginning of each session, the house light was turned on and the lever inserted. At the end of each session, the light was turned off and the lever retracted. Mice were trained in an initial lever-press training consisting of 4 consecutive days of CRF, during which the mice received a pellet for each lever press. A session would end after 60 min or after the mouse had collected 30 rewards, whichever came first. After CRF, mice were trained with RI schedules to generate habitual lever pressing (Dickinson et al., 1983). The training started with 2 days on RI 30 s, with a 0.1 probability of reward availability every 3 s contingent on lever press, and followed by 6 days on the 60 s interval schedule, with a 0.1 probability of reward availability every 6 s contingent on lever pressing. Repeated-measures ANOVA was used to compare lever press between the different genotypes.

Devaluation Tests

A specific satiety procedure was used for outcome devaluation. Mice were given unlimited access within a fixed duration to either the mouse chow to which they had been exposed in their home cages (nondevalued condition/control), or the purified pellets they normally earned during lever-press sessions (devalued condition). The mouse chow served as a control for overall level of satiety. This procedure controls the overall level of satiety and motivational state, while altering the current value of a specific reward. Immediately after 1 hr of unlimited exposure to the pellets or chow, the mice were subjected to a 5 min long probe test. During the probe test the lever was inserted, but no pellet would be delivered in response to lever pressing. This brief extinction test was designed to test whether the acquired lever pressing of the mice was controlled by the action-outcome instrumental contingency or habit (e.g., in response to a antecedent stimuli). On the second day of outcome devaluation, the same procedure was used, except that those animals that received mouse chow on day 1 received pellets on day 2, and vice versa. When grouping, mice were counterbalanced between genotypes and treatment. Repeated-measures ANOVA and unpaired Student's t test were used to compare lever press between the different genotypes as specified in the text.

Plus Maze

The maze consisted of four arms measuring 35 cm long, 6 cm wide, and 35 cm deep, with transparent high walls made of clear Plexiglas. For training positively reinforced with food pellets (20 mg per pellet), animals were maintained at 80%–75% of their free-feeding weight throughout the experiment. For training negatively reinforced with water, water was stained opaque and white with titanium dioxide. A hidden platform was placed 1 inch under the water surface. The training and testing were as described in the text. For plus maze assays, littermates in Slc6a3+/Cre, fNR1/+ (control), Slc6a3+/Cre (Cre control), and wild-type genotypes were chosen as three control groups. Turning of mice in different tests was compared using chi-square tests, as specified in the text, to evaluate the performance of mice from different genotypes. Additionally, repeated-measures ANOVA and unpaired Student's t test, as specified in the text, were used to compare time spent in different arms among mice from the different genotypes.

Zigzag Maze

The shape of the zigzag maze is illustrated in Figure 8A. Each arm measures about 30 cm long, 6 cm wide, and 35 cm deep. The maze was filled with water that was stained opaque and white with titanium dioxide. A hidden platform was placed at a designed location 1 inch under the water surface. Training and tests were done as described in the text. The chi-square test and Fisher's exact test were used to compare the performance of mice from different genotypes.

Surgeries

A 32-channel (a bundle of 8 tetrodes), ultralight (weight <1 g), movable (screw-driven) electrode array was constructed similar to that described previously (Lin et al., 2006; Wang and Tsien, 2011). Each tetrode consisted of four 13 μm diameter Fe-Ni-Cr wires (Stablohm 675, California Fine Wire; with impedances of typically 2–4 MΩ for each wire) or 17 μm diameter Platinum wires (90% Platinum 10% Iridium, California Fine Wire; with impedances of typically 1–2 MΩ for each wire). One week before surgery, mice (3–6 months old) were removed from the standard cage and housed in customized home cages (40 × 20 × 25 cm). On the day of surgery, mice were anesthetized with ketamine/xylazine (80/12 mg/kg, i.p.); the electrode array was then implanted toward the VTA in the right hemisphere (3.4 mm posterior to bregma, 0.5 mm lateral and 3.8–4.0 mm ventral to the brain surface) and secured with dental cement.

Tetrode Recording and Unit Isolation

Two or three days after surgery, electrodes were screened daily for neural activity. If no dopamine neurons were detected, the electrode array was advanced 40–100 μm daily, until we could record from a putative dopamine neuron. Multichannel extracellular recording was similar to that described previously (Lin et al., 2006; Wang and Tsien, 2011). In brief, spikes (filtered at 250–8000 Hz; digitized at 40 kHz) were recorded during the whole experimental process using the Plexon Multichannel Acquisition Processor System. Mice behaviors were simultaneously recorded using the Plexon CinePlex tracking system. Recorded spikes were isolated using the Plexon Offline Sorter software: multiple spike sorting parameters (e.g., principle component analysis, energy analysis) were used for the best isolation of the tetrode-recorded spike waveforms. Combining the stability of multi-tetrode recording and multiple unit-isolation techniques available in Offline Sorter (e.g., principle component analysis, energy analysis), individual VTA neurons can be studied in great detail, in many cases for days.

Reward Conditioning of DA Neurons

Mice were slightly food restricted before reward association training. In reward conditioning, mice were placed in the reward chamber (45 cm in diameter, 40 cm in height). Mice were trained to a tone (5 kHz, 1 s) with subsequent sugar pellet delivery for at least 3 days (40 trials per day; with an interval of 1–2 min between trials). The tone was generated by the A12-33 audio signal generator (5 ms shaped rise and fall; about 80 dB at the center of the chamber) (Coulbourn Instruments). A sugar pellet (14 mg) was delivered by a food dispenser (ENV-203-14P; Med. Associates) and dropped into one of two receptacles (12 × 7 × 3 cm) at the termination of the tone (the other receptacle was used as control, where a sugar pellet was never received).

Analysis of In Vivo Recording Data

Sorted neural spikes were processed and analyzed in NeuroExplorer (Nex Technologies) and MATLAB. Dopamine neurons were classified based on the following three criteria.

(1) Low baseline firing rate (0.5–10 Hz).
(2) Relatively long ISI (all the classified putative dopamine neurons are with ISIs >4 ms within a ≥99.8% confidence level). The shortest ISI we recorded was 4.1 ms under any conditions in our experiment (only well-isolated units with amplitude ≥0.4mV were used for calculation of the shortest ISI). The averaged shortest ISI was 6.8 ± 2.2 ms (mean ± SD; n = 36). In contrast the ISI for nondopamine neurons can be as short as 1.1 ms.
(3) Regular firing pattern when mice were freely behaving (fluctuation <3 Hz). Here, fluctuation represents the SD of the firing rate histogram bar values (bin = 1 s; recorded for at least 600 s).

SUPPLEMENTAL INFORMATION

Supplemental Information includes one figure and Supplemental Experimental Procedures and can be found with this article online at doi:10.1016/j.neuron.2011.10.019.

ACKNOWLEDGMENTS

We thank Fengying Huang and Brianna Klein for technical assistance. This work was supported by funds from NIMH, NIA, and Georgia Research Alliance (all to J.Z.T.). L.P.W., F.L., X.S., and J.Z.T. conceived and designed the experiments. L.P.W., F.L., D.W., K.X., and D.H.W. performed the experiments. L.P.W., F.L., D.W., K.X., and J.Z.T. analyzed the data. L.P.W., F.L., X.S., and J.Z.T. contributed reagents/materials/analysis tools. L.P.W., F.L., K.X., and J.Z.T. wrote the paper. All experiments involving animals were performed according to procedures approved by the Georgia Health Sciences University IACUC review board.

Novelty-Seeking DRD4 Polymorphisms are Associated with Human Migration Distance Out-of-Africa After Controlling for Neutral Population Gene Structure

KEY WORDS functional polymorphisms; novelty-seeking trait (NS), natural selection; cultural neuroscience; human variation

ABSTRACT Numerous lines of evidence suggest that *Homo sapiens* evolved as a distinct species in Africa by 150,000 years before the present (BP) and began major migrations out-of-Africa ~50,000 BP. By 20,000 BP, our species had effectively colonized the entire Old World, and by 12,000 BP *H. sapiens* had a global distribution. We propose that this rapid migration into new habitats selected for individuals with low reactivity to novel stressors. Certain dopamine receptor D4 (DRD4) polymorphisms are associated with low neuronal reactivity and increased exploratory behavior, novelty seeking, and risk taking, collectively considered novelty-seeking trait (NS). One previous report (Chen et al.: Evol Hum Behav 20 (1999) 309–324) demonstrated a correlation between migratory distance and the seven-repeat (7R) VNTR DRD4 allele at exon 3 for human populations. This study, however, failed to account for neutral genetic processes (drift and admixture) that might create such a correlation in the absence of natural selection. Furthermore, additional loci surrounding DRD4 are now recognized to influence NS. Herein we account for neutral genetic structure by modeling the nonindependence of neutral allele frequencies between human populations. We retest the DRD4 exon 3 alleles, and also test two other loci near DRD4 that are associated with NS. We conclude there is an association between migratory distance and DRD4 exon 3 2R and 7R alleles that cannot be accounted for by neutral genetic processes alone. Am J Phys Anthropol 145:382–389, 2011. © 2011 Wiley-Liss, Inc.

Dopamine neurotransmission is fundamental to human appetitive and reward-seeking behaviors, movement, cognition, and sociability. DRD4 is a metabotropic inhibitory receptor, which acts to decrease intracellular adenylyl cyclase production following dopamine binding (Van Tol et al., 1991; Oldenhof et al., 1998). Neuroanatomically, DRD4 is differentially expressed, with the prefrontal cortex containing the highest density of receptors that act to inhibit downstream neural firing (Dulawa et al., 1999).

Humans exhibit several DRD4 polymorphisms, which include a well-described 48 base-pair (bp) variable number tandem repeat (VNTR) in exon 3 (Ding et al., 2002; Grady et al., 2003). The most common VNTR alleles are 2-, 4-, and 7-repeats (2R, 4R, 7R), which together account for over 90% of all variation at this locus (Chang et al., 1996; Ding et al., 2002). Across all human populations 4R allele frequencies are highest, 2R is common in Asians but rare in Native Americans, and 7R is common in the Americans but rare in Asians and Africans (Chang et al., 1996; Wang et al., 2004). 7R and 2R alleles are associated with a partial loss of DRD4-mediated prefrontal inhibition because of blunted second messenger response. Compared with the 4R, the 2R and 7R alleles result in 40 and 80% reduction in intracellular second messenger response, respectively (Asghari et al., 1995; Wang et al., 2004).

Promoter polymorphisms, including a −521 C/T single nucleotide polymorphism (SNP) and a 120-bp tandem duplication located 1.2 kilo-bp upstream of the initiation codon, are associated with similar neurophysiologic downstream effects as 2R and 7R exon 3 VNTR alleles (Kamakura et al., 1997; Seaman et al., 1999; Lowe et al., 2004). There is a well-supported correlation between the DRD4 7R, 2R, 120-bp promoter duplication, and −521 C/T SNP and the personality trait *novelty seeking* (NS) (Tomitaka et al., 1999; Tsai et al., 2004; Reist et al., 2007; Munafò et al., 2008). High NS individuals are considered exploratory, impulsive, excitable, quick-tempered, and extravagant, whereas low NS individuals tend to be rigid, prudent, stoic, reflective, staid, and slow-tempered (Cloninger et al., 1991; Ebstein et al., 1996).

Chen et al. (1999) suggested that global population patterning of 4R and 7R frequency variation can be explained by increased migratory distances of NS individuals (7R variant) compared with that of low NS individuals (4R variant). They proposed NS individuals represented a behavioral phenotype that functioned better under the novel ecological and social circumstances imposed during migration such that migration effectively

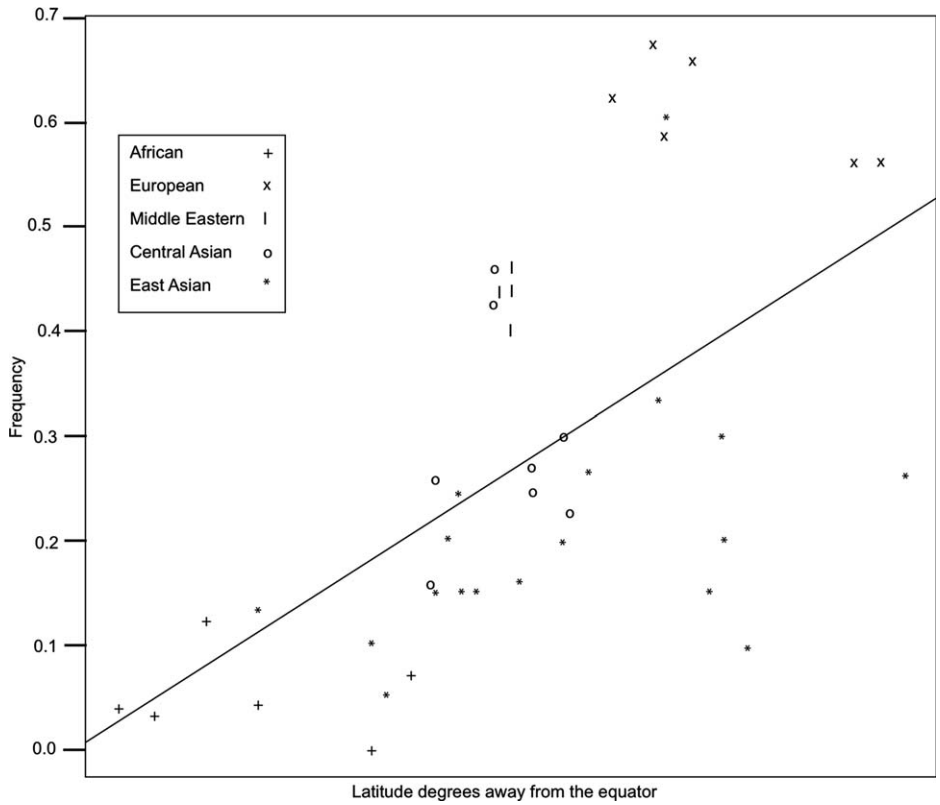

Fig. 1. (Redrawn from Coop et al., Genetics 2010, 185:1411–1423) The effect of statistical nonindependence of population genetic data. The frequencies shown are for a single SNP allele, AGT M235T, in various populations plotted against latitude. Note how populations from the same region frequently cluster on the same side of the regression line, which indicates their statistical nonindependence. Independent data points would scatter randomly across the regression line. The situation is highly analogous to the more well-characterized nonindependence that arises at the species level in a phylogenetic context (Rendall and Di Fiore, 1995; Rohlf, 2006).

selected for NS alleles. They found no association between 7R frequencies and recent migration to the United States by Europeans and East Asians, suggesting that 7R carriers are *not prone to migrate*, but that they may experience higher fitness in response to many generations of migration. This selection hypothesis proposes that migration presents novel ecological and social circumstances which NS individuals deal with more effectively, with less stress response, and thereby experience greater fitness relative to low NS individuals.

Alternatively, if decisions by individuals in recent migrations are fundamentally different from those in ancient migrations, then it could be that NS individuals during ancient migrations were actually more prone to migrate. This nonselection hypothesis still specifies a correlation between migration distance and NS alleles, but the correlation comes about through genetically based tendencies in the decisions of NS individuals.

In this study, we do not attempt to distinguish between these alternative processes (selection or biased decisions based on genotype) that would result in a correlation of NS alleles and migratory distance. Instead, we seek to determine if the correlation itself can be accounted for by neutral genetic processes alone; that is, is it necessary to invoke one of the above non-neutral processes patterning variation in NS alleles? We retested Chen et al.'s (1999) findings for the 7R allele in conjunction with three other alleles (exon 3 VNTR 2R allele, −521 C/T SNP, 120-bp duplication), while controlling for the effects of population history and admixture.

We controlled for neutral genetic processes by using the results of a major recent global genetic survey (Tishkoff et al., 2009) to construct a correlation structure that expressed the correlations expected to arise by drift and admixture in gene frequencies among human populations. Because the out-of-Africa migration proceeded though a process of serial colonization, significant population size bottlenecks have occurred throughout the history of human migration across the globe (Ramachandran et al., 2005; Li et al., 2008; DeGiorgio et al., 2009; Deshpande et al., 2009; Hunley et al., 2009). Thus, observed associations of migratory distance and particular allelic frequencies may result simply from cumulative effects of genetic drift that skew allele frequencies more dramatically with increasing distance from Africa (Klopfstein et al., 2006). This problem exists for any association of a particular allele frequency and an ecological trait, not just migratory distance (Coop et al., 2010; Hancock et al., 2010). In particular, Coop et al., (2010) have proposed that because drift does not systematically affect the frequency of any particular allele, human populations out of Africa only show shared patterns of allelic differentiation because they share the same stochastic drift events. This renders human populations as statistically nonindependent (see Fig. 1). We return to this point in more detail in the Discussion. As pursued by other authors (Coop et al., 2010; Hancock et al., 2010) we attempted to control for neutral genetic processes by attacking the fundamental problem of data point nonindependence with a correlation structure in a generalized

linear model. The correlation structure expressed the expected correlations among population data points under a model of neutral genetic change, and transformed the DRD4 data to remove neutral genetic effects through a likelihood-based linear regression model. We assessed the performance of our correlation structure with a set of previously published neutral loci.

We also used the same neutral loci in an alternative test of the specific association of migratory distance and NS alleles by assessing whether the residual variation of migratory distance regressed on DRD4 alleles was less than exhibited by similar regressions with neutral genetic loci. We asked if frequencies of NS alleles at DRD4 showed a tighter increase with migratory distance than we would expect by chance, chance being reflected in this case by neutrally evolving loci.

MATERIALS AND METHODS

Functional gene data

We searched the published literature for loci surrounding DRD4 with well-characterized in vitro effects on expression or binding, well-characterized effects on personality traits, and with population level sampling from groups whose neutral genetic structure was known. We found 3 loci that were available across 15 or more human populations (Chang et al., 1996; Chen et al., 1999; Osier et al., 2002; Rajeevan et al., 2003; ALFRED, http://alfred.med.yale.edu). These loci were DRD4 exon 3 VNTRs, −521 C/T SNP, and the promoter region 120-bp duplication.

Migratory distance

We derived population locations from the midpoint of the geographic range reported in ALFRED (http://alfred.med.yale.edu; midpoint calculations–http://www.movable-type.co.uk/scripts/latlong.html). We calculated the migratory distance of each population in our study as the great circle distances connecting them across the globe and along known routes of human migration out-of-Africa (Prugnolle et al., 2005; Liu et al., 2006, Mellars, 2006; Long et al., 2009; calculations performed in Google Earth). We set the San as migratory point zero because they were the most anciently diverged population of those included in our study and because they are genetically close to the origin within Africa of human genetic diversity as inferred through coalescent models (Tishkoff et al., 2009). Thus, within Africa we constructed the following routes (San → Mbuti, San → Bantu → Hausa/Biaka). All routes out of Africa went through the Mbuti in central Africa, and then the Druze in the Levant. European and Near Eastern routes led from the Druze directly to Sardinian and Adygei. We constructed a southern route through Asia as Druze → Cambodian → Papuan → Melanesian. A more Northern route through Asia led to the Han followed by the Japanese. The route to the Americans went through the Han and then direct to the Yakut, followed by the New World populations in a North to South sequence. These migration values thus attempt to capture the minimum migratory distance of populations from the origins of our species to their present locations, relative to the other populations in the study. They may underestimate the actual distances that populations have migrated since their inception as distinct demes.

Neutral genetic structure

We controlled for neutral genetic processes of drift, admixture, and the history of population separations by incorporating published D^2 genetic distances into a generalized least squares linear model (see Comparative Analyses below). The D^2 expresses the expected allele frequency differentiation between two populations under an evolutionary model with no selection or mutation (Reynolds et al., 1983). We obtained distances from a recent global study of human genetic differentiation that used data from 1327 polymorphic and neutrally evolving loci from 3945 individuals (Tishkoff et al., 2009).

Comparative analyses

We constructed a generalized least squares (gls) statistical model with migratory distance as the dependent variable and with three independent variables (implemented in R, package "nlme", Pinheiro et al., 2009). One independent variable was the summed frequency for DRD4 2R and 7R alleles, because higher frequencies of *either* allele should produce similar phenotypic effects in the form of increased NS behavior. The other two independent variables were the frequencies of the T SNP at position −521, and the frequencies of the promoter region 120-bp duplication. All independent variables were coded as fixed effects, with the prediction that higher frequencies of each would be associated with greater migratory distance. Because the variance distribution of frequency data rarely conform to assumptions of linear modeling, we arcsine transformed the raw frequency data for subsequent analysis (Sokal and Rohlf, 1995, pp 419–422).

We included a correlation structure in our model to control for the nonindependence of data points in this study (Dow et al., 1984; Pinheiro and Bates, 2000; Rohlf, 2006; Dow, 2007; Coop et al., 2010; Hancock et al. 2010). The allele frequencies of human populations are rendered statistically nonindependent because they share complex histories of drift and admixture that stochastically alter the frequencies of all alleles, including those that are selectively neutral. Chen et al., (1999) recognized this nonindependence, but dealt with it insufficiently by simply scoring whether pairs of populations participated in the same migration routes. Here, we account for the nonindependence with robust measures of genetic distance between populations from neutrally evolving loci. We converted the D^2 distances into expected correlations within the study sample by applying the linear transformation:

$$(\max(D^2) - D^2_{ij}) / \max(D^2)$$

where $\max(D^2)$ is the maximum distance in the matrix and D^2_{ij} is the observed distance between a given pair *i, j*. This transformation produced a matrix of expected correlations among data points ranging from 0 for the two most divergent populations to 1 for each population to itself. This correlation matrix is thus directly analogous in its range of expected correlations to the matrices used in phylogenetic generalized least squares analyses between species (Pagel, 1999; Garland and Ives, 2000; Rohlf, 2006; Coop et al., 2010), but it does not presume bifurcating relationships among the study taxa.

Using our correlation structure to control for neutral population genetic processes, we constructed least squares regression models from each possible combination of the three independent variables, and used Akaike Information

Criterion (AIC) and likelihood ratio tests (LRT) to select the best model. We then assessed the significance of the remaining independent variables through *t*-tests of the slope residuals.

To assess how well our D^2-derived correlation matrix controlled for neutral genetic processes in our final model, we also ran our model with a subset of the neutral alleles used by Tishkoff et al., (2009) to calculate genetic distances. We used the 405 microsatellite and duplication loci provided online by Tishkoff et al., (2009) that were variable for the populations in our study. The full data set used by Tishkoff et al., (2009) for the D^2 calculation includes all alleles at 1327 loci. For each of the 405 loci, we selected one allele at random from individuals in the populations of our final model. We calculated the frequency of these random alleles within each population, applied the arcsine transform to the frequencies, and then ran the same gls analyses for each allele both with and without our correlation structure. When using our correlation structure to control for neutral genetic processes, ideally only 5% of these neutral loci would show a significant association with migratory distance at the 0.05 nominal level for significance. Because the human populations are nonindependent data points, we expected much higher rates of type 1 error (false positives) when the correlation structure was not used.

We also conducted an alternative test of NS alleles that were deemed significant in our linear model with a correlation structure. In this test, we ran a standard least squares regression of migratory distance on the NS allele frequency. If the observed association in fact arose by neutral evolutionary processes, then the goodness of fit between increases in migratory distance and NS allele frequencies should be no stronger than that observed between migratory distance and each of the 405 neutral loci. One standard measure of goodness of fit in a regression model is the residual variation from the best fit regression line. We calculated the residual variation for the best fit model of each of the 405 neutral loci and migratory distance. We subtracted the absolute residual deviations of each of the 405 neutral loci from the absolute residuals from the NS allele frequencies. If the association of NS allele frequencies and migratory distance were no different than that expected under neutral evolution, then on average about half of the neutral loci would have larger residuals and half would have smaller residuals than from the NS allele frequencies. If the association of NS allele frequencies and migratory distance is more than expected to arise from neutral processes, then the difference in residuals should be significantly negative, as the NS residuals should be much smaller than typical of a neutral allele—indicative of a tighter than expected association with migratory distance. We tested whether the calculated differences in residuals were significantly negative with a one-sample Wilcoxon signed rank test.

RESULTS

We assessed which independent variables should be included in the model for migratory distance through a likelihood analysis of all the data points without any missing values (Table 1). The best-supported model to explain out-of-Africa migratory distance included the composite 2R/7R DRD4 allele frequencies (Table 2). The model with this single predictor variable had a better AIC value than all other models. The next most complex models that additionally included either the 120-bp duplication, or the −521 T SNP (see Table 2), did not sufficiently improve the likelihood of the data under the likelihood ratio test ($P = 0.193$). Within the most complex model that included all three predictor variables, variance inflation factors for colinearity among the independent variables were low (2R/7R = 1.4, 120-bp duplication = 1.3, −521 T SNP = 1.3; R package "Design", Harrel, 2009). This indicates that allele frequencies at the loci are largely independent of one another and the alleles at alternative loci can be regarded as unlinked.

The *t*-test of slope residuals in our best model showed a significant positive relationship between the DRD4 2 + 7 repeat elements and migratory distance ($\beta = 18687$, $P = 0.018$, two-tailed, 16 df; Fig. 2). Thus, the summed frequency of 2 and 7 repeat element alleles was more associated with migratory distance than expected by chance.

TABLE 2. Models ordered by AIC value

Model	AIC	log Likelihood
r	265.0	−129.5
r,d	265.3	−128.7
r,s	265.3	−128.7
r,s,d	266.3	−128.1
s	266.6	−130.3
d,s	268.6	−130.3
d	269.7	−131.9

r = DRD4 2 + 7 repeat frequency; d = 120-bp duplication frequency; s = −521 T SNP frequency.

Our tests of 405 neutral markers from Tishkoff et al., (2009) revealed that Type I error rates (false positives) were somewhat elevated under the assumption that the these markers were neutral with respect to selection pressures correlated with migratory distance (observed error = 0.12, expected error = 0.05, z-test of proportions, $P < 0.001$). However, the slope estimates for the neutral loci were not biased up or down, rather they were centered on zero (mean $\beta = 99.3$, t-test for difference from 0, $P = 0.833$, two-tailed). The correlation structure, however, greatly improved the error rate when compared with gls models of the neutral markers that lacked any correction for the nonindependence of the data points (observed error = 0.457). Although the mean of slope estimates from these reduced gls models was more extreme (mean $\beta = -241$) than in the models that included a correlation structure, the estimated slopes again were not significantly different from zero ($P = 0.84$, two-tailed t-test). This can occur because the variance of the slopes across the models without a correlation structure ($\sigma^2 = 6.05 \times 10^8$) was an order of magnitude greater than the variance from slope estimates that used a correlation structure ($\sigma^2 = 8.94 \times 10^7$, Fig. 3).

Given this evidence for slightly inflated Type I error (0.118 instead of 0.05), we corrected the P-value for the significant 2R/7R result based on the observed inflation of error in the neutral loci (a factor of 2.36). The 2R/7R result remained significant after this correction (corrected $P = 0.042$, two-tailed).

The residual variation migratory distance and the DRD4 2 + 7 allele frequency was significantly less than that observed at the 405 neutral loci (median difference in NS and neutral residuals = −3040 km, Wilcoxon signed rank test, $P < 0.001$)

DISCUSSION

This study supports that higher frequencies of novelty seeking (NS) 2 and 7 R alleles at DRD4 exon 3 are associated with population histories of migration, which confirms previous findings specific to the 7R alleles (Chen et al., 1999). Because the out-of-Africa migration proceeded though a process of serial colonization, significant and demographically shared population size bottlenecks have occurred throughout the history of human migration across the globe (Ramachandran et al., 2005; Li et al., 2008; DeGiorgio et al., 2009; Deshpande et al., 2009; Hunley et al., 2009). Thus, observed associations of migratory distance and allelic frequencies may result simply from cumulative effects of genetic drift that skew allele frequencies more dramatically with increasing distance from Africa (Klopfstein et al., 2006). Our study is the first to demonstrate that neutral genetic processes of drift and/or admixture, which produce statistical nonindependence among population data points, cannot explain the association between higher frequencies of NS alleles in DRD4 exon 3 and migration distance.

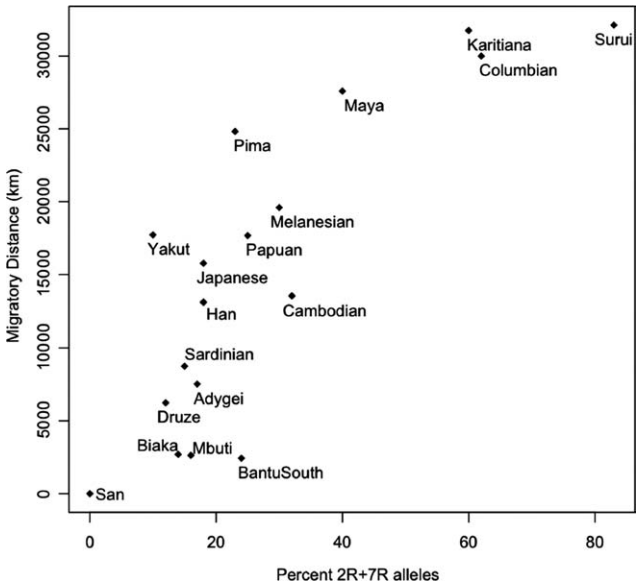

Fig. 2. Migratory distance out-of-Africa versus summed 2R and 7R DRD4 exon 3 alleles.

The gls statistical model with a correlation structure to remove the effects of shared genetic ancestry, admixture, and drift was largely successful. The low variance inflation factors indicate that, with respect to the association with migratory distance, the loci we tested can be regarded as statistically unlinked. Although the correlation structure we used did not reduce the rate of Type I errors (false positive results) to their expected value of 0.05, it did substantially improve the Type I error rate. This marked improvement of the error rate strongly suggests, as proposed recently by other researchers, that statistical associations of allelic frequencies and ecological traits caused by neutral evolution arise primarily from the statistical nonindependence of human populations as data points (Coop et al., 2010; Hancock et al., 2010). Although derived alleles may show a tendency for higher frequency outside Africa as a result of range expansion (Klopfstein et al., 2006), the association in a linear model of the frequencies of neutral alleles and distance from Africa is not biased, as is reflected by the slopes of the neutral loci being centered on zero. As shown in Figure 3, even when we did not control for neutral population structure, the estimated slopes were centered on zero. The fact that using the correlation structure reduced the slope variance while keeping it centered on zero shows that the statistical nonindependence of intraspecific populations behaves much the same as the nonindependence of interspecific datapoints in a phylogenetic context (Martins and Garland, 1991; Rendall and Di Fiore, 1995; Garland et al., 2005; Rohlf, 2006; see also Coop et al., 2010). Phylogenetic nonindependence is well-known to increase the variance of slope estimates and thus inflate Type I error, but it does not systematically bias these estimates; they remain centered on zero (Rohlf, 2006).

This being said, our correlation structure did not reduce the Type I error to its expected level. This can occur if the correlation structure is somewhat miss-specified, in that it does not fully reflect the true process that generated the nonindependence of the data (Martins and

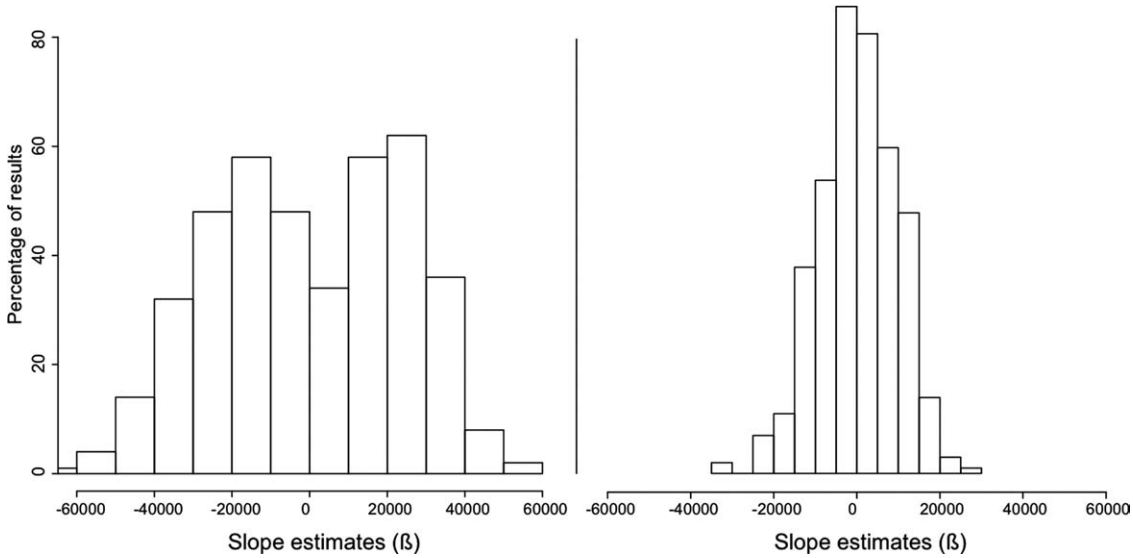

Fig. 3. Histograms of the slope estimates from migratory distance regressed on each of the 405 neutral alleles. The right panel shows the estimates from a least squares model without any adjustment for population data point nonindependence. The left panel shows slopes from the same loci from a model that used our correlation structure to control for the nonindependence that arises from drift and admixture. Note that all estimates are centered on zero (i.e., they are neutral), and that the use of the correlation structure greatly reduces the variance of the estimated slopes.

Garland, 1991; Rohlf, 2006). For example, one factor that may have contributed to miss-specification could be that the D^2 distance does not allow for frequency differences to arise from mutation or from types of selection that may be difficult to detect within the largely neutral markers (e.g., purifying and balancing selection). We expect that future research will enable such miss-specifications to be corrected by using optimizing transformations of the correlation structure based on the dependant and independent variables used in the linear model. Such procedures have recently become routine in the context of phylogenetic generalized least squares (Garland et al., 2005). Some common transformations of the phylogenetic correlation structure to reflect the inferred evolutionary process include the multiplier lambda and the exponential transform rho, both of which control for reduced phylogenetic signal, as well as the exponential transform kappa that reflects speciational evolution (Grafen, 1989; Pagel, 1999). The inflation of Type I error in our study is only slightly greater than observed in phylogenetic simulations before the implementation of such transformations of correlation structures (Martins and Garland, 1991).

Developing appropriate transformations for intraspecific correlation structures is beyond the scope of this study. Thus, we elected to correct the *P*-value from the DRD4 2R/7R result by the inflation of Type I error observed among the neutral loci. The 2R/7R result remained significant after this correction. The residual variation from a least squares regression of migratory distance on DRD4 2 + 7 repeat allele frequency was also significantly less than the residual variation observed among neutral loci.

These results also suggest a strong warning to recent publications by psychologists and others that have heralded the advent of a new "cultural neuroscience" research program (Chiao and Blizinsky, 2009; Chiao et al., 2010; Goldman et al., 2010; Kitayama and Park, 2010; Kitayama and Tompson, 2010; Way and Lieberman, 2010). This program is based on finding associations of gene frequencies with behavioral and ecological traits across human groups but does not incorporate the effects of neutral genetic processes. One example, published recently in AJPA, purported to find evidence of NS alleles of DRD4 being linked to hunter-gatherer lifestyles among Native South Americans (Tovo-Rodrigues et al., 2010). We agree that such a research program, properly conducted, will yield important scientific insights. None of these studies, however, have accounted adequately for the nonindependence of human populations. Tovo-Rodrigues et al. (2010) made no accommodation for the role of neutral evolution of allele frequencies. Both Chiao and Blizinsky (2009) and Way and Lieberman (2010) attempted to deal with nonindependence by lumping data points into similar cultural regions. Anthropologists have demonstrated, however, that such approaches fail to remove the nonindependence that still exists among the lumped cultural regions (Dow, 1984; Mace and Pagel, 1994; Eff, 2004; Dow, 2007). Cultural regions, furthermore, express cultural and linguistic linkages among people and are not designed to reflect the population genetic structure that determines the nonindependence of allele frequencies.

In short, treating human populations as statistically independent treats them as something that profoundly they are not. Populations exhibit complex histories of separation, drift, and admixture, and ignoring this is a serious methodological error that will inflate Type I error, reduce statistical power, and thereby produce many erroneous conclusions.

We found no support for an association between migratory distance and two promoter region loci at DRD4 that alter the expression levels of this gene and mediate NS as measured through psychological surveys. Although the inclusion of more data points may change this result, these negative results are not likely the product of low power, as the power to detect the observed simple Pearson correlation of the 2R/7R frequencies and migratory distance was 0.96 (R package "pwr", Champely, 2009). These promoter loci may not, in fact, correlate with dispersal distance if their phenotypic effects are more greatly influenced by gene X gene and gene X environ-

ment interactions than are the effects of the 2R/7R allele located within exon 3. Given that convergent phenotypic change can often reflect nonconvergent underlying genetic changes (Tishkoff et al., 2006), studies like ours may be able to detect only those loci with highly robust phenotypic effects. Though few, such loci are important to medical intervention, because doctors in their clinical practice are able at present to test for genetic variation at target alleles, whereas diagnoses based on complete individual genotyping may still lie far in the future.

We hope our positive results for DRD4 exon 3 will motivate more research on this topic that will include sampling of both functional and neutral markers from human populations of known provenience. Unfortunately, no such sample exists at present for DRD4 alleles nor for other loci that would be good candidates for selection by migration effects, specifically the serotonin transporter 5-HTT and monoamine oxidase A (Nakamura et al., 2000; Lea and Chambers, 2007). The paucity of data has health consequences because all these loci are linked to a variety of psychopathologies (Caspi et al., 2003; Canli and Lesch, 2007; Guo et al., 2008). Population-level sampling and the resultant better understanding of the functionality of these loci would likely result in better treatment outcomes for patients than do the current common practices of genetic profiling based on broad ethnic labels. Such labels confound genetic and cultural forms of variation (e.g., Munafò et al., 2003; Chiao and Blizinsky, 2009). Genetic and cultural identities frequently overlap, but just as frequently they are disjoint or intersect in complex ways (Risch et al., 2002; Hunley et al., 2009; Long et al., 2009). We can only understand these interactions if we first sample both genetic and cultural systems in ways that are most appropriate to their particular modes of inheritance and distributions of variation.

In summary, we found significant support for dispersal distance during the out-of-Africa migrations being associated with higher frequencies of NS alleles in DRD4 exon 3. Given the findings of Chen et al., (1999) that these alleles did not induce migration within a single generation, the likely best explanation of our observed association is that NS individuals experience higher fitness during migrations. Migration distance, thus, effectively selects for NS phenotypes and associated alleles even though NS individuals may be no more prone to migrate than are other individuals. The atypical pattern of variation in the 7R VNTR of DRD4 exon 3 suggests it emerged as a recent mutational event ~40–50 Ka BP (Ding et al., 2002) and is under positive Darwinian selection (Wang et al., 2004). This coalescence time is roughly coincident with the first observed wave of migration of modern humans from Africa and into Europe and Asia. The coalescence time, genetic signature of selection, and observed association with migratory distance, are all highly consistent with the hypothesis that increased frequencies of 2R and 7R exon 3 VNTRs have been selected by repeated generations of migration.

ACKNOWLEDGMENTS

The authors report no conflicts of interest. The authors thank Patrick McNamara, Charles Nunn, the lab group of Richard Wrangham, and especially Amanda Lobell for helpful discussions on this research. Amanda Lobell and Jason Hodgson provided helpful comments on the manuscript and analysis. The authors also thank Sarah Tishkoff for providing the D^2 distances. The authors thank the Editor-in-Chief, the Associate Editor, and the two anonymous reviewers for their helpful comments on the manuscript.

REVIEW ARTICLE

A unified model of the pathophysiology of bipolar disorder

Abstract

This work provides an overview of the most consistent alterations in bipolar disorder (BD), attempting to unify them in an internally coherent working model of the pathophysiology of BD. Data on immune-inflammatory changes, structural brain abnormalities (in gray and white matter), and functional brain alterations (from neurotransmitter signaling to intrinsic brain activity) in BD were reviewed. Based on the reported data, (1) we hypothesized that the core pathological alteration in BD is a damage of the limbic network that results in alterations of neurotransmitter signaling. Although heterogeneous conditions can lead to such damage, we supposed that the main pathophysiological mechanism is traceable to an immune/inflammatory-mediated alteration of white matter involving the limbic network connections, which destabilizes the neurotransmitter signaling, such as dopamine and serotonin signaling. Then, (2) we suggested that changes in such neurotransmitter signaling (potentially triggered by heterogeneous stressors onto a structurally-damaged limbic network) lead to phasic (and often recurrent) reconfigurations of intrinsic brain activity, from abnormal subcortical–cortical coupling to changes in network activity. We suggested that the resulting dysbalance between networks, such as sensorimotor networks, salience network, and default-mode network, clinically manifest in combined alterations of psychomotricity, affectivity, and thought during the manic and depressive phases of BD. Finally, (3) we supposed that an additional contribution of gray matter alterations and related cognitive deterioration characterize a clinical–biological subgroup of BD. This model may provide a general framework for integrating the current data on BD and suggests novel specific hypotheses, prompting for a better understanding of the pathophysiology of BD.

Introduction

Bipolar disorder (BD) is defined by the occurrence of active episodes of mania and depression, which show opposite constellations of disturbances in psychomotricity, affectivity, and thought, along with asymptomatic periods of euthymia [1, 2]. BD is a prevalent, severe, and debilitating psychiatric disorder, and the understanding of its pathophysiology represents a major challenge for contemporary research in psychiatry and neuroscience [1, 3].

In the last decades, a number of robust and consistent alterations have been detected in BD across diverse areas of research, including immune-inflammatory changes, structural brain abnormalities (in gray and white matter), and functional brain alterations (from neurotransmitter signaling to intrinsic brain activity) [4–9]. However, the relationship between these core alterations in BD is complex and still unclear.

Therefore, in this work, we provide an overview of the most consistent findings on BD, along with the results from our work on this topic, attempting to unify them in an internally coherent working model of the pathophysiology of BD.

Data overview on bipolar disorder

Immunological alterations

Evidences of immune dysregulation and inflammation in psychiatric disorders including BD have been accumulated

since the 1980s, as firstly described by Maes and other Authors, concerning both cytokines and immune cells, in the peripheral circulation and central nervous system [5, 10–15]. In particular, levels or activity of pro-inflammatory cytokines, e.g., interleukin (IL)-6, tumor necrosis factor (TNF)α, interferon (IFN)γ, and other soluble factors such as C-reactive protein (CRP), were found to be consistently elevated in the active phases of BD, mania and depression, with complete or partial normalization during euthymia [16, 17]. Notably, a longitudinal investigation showed that manic episodes were accompanied by state-dependent inflammatory activation (i.e., increased IL-6 and CRP levels) [18]. Moreover, activation of T cells with increased circulating levels of CD4+ T cells and decreased levels of CD8+ T cells, along with activation and increased peripheral levels of monocytes and activation of microglia, have been consistently detected in BD [13, 19–25]. In our previous work, we further specified the T cell alterations in BD, by showing in the peripheral circulation an increase in the early generated CD4+(CD28+) T cells along with a decrease in the differentiated effector CD8+(CD28−) T cells (effector memory, terminal effector memory, and IFNγ-producing CD8+ T cells) [26]. This pattern was strongly associated to BD patients recruited during mania, while less evident in patients recruited during depression or euthymia [26].

Together, these data may suggest that BD is associated to immune activation with a predominant pro-inflammatory profile.

Gray and white matter brain alterations

A large amount of structural neuroimaging data on psychiatric disorders has been accumulated since the 1990s and gray matter (GM) abnormalities were found in BD, although with heterogeneous results [27, 28]. No altered GM volumes were found in first episode and early stage of BD [29, 30]. However, evidence of widespread neuroprogressive loss of GM volume, especially in the frontal areas, has been demonstrated in longitudinal studies and associated with longer illness duration, and this has been related to progressive cognitive deterioration in BD [31, 32].

White matter (WM) abnormalities resulted to be a consistent finding in BD, as shown by several structural imaging studies since the 1990s and diffusion magnetic resonance imaging (dMRI) studies since the 2000s [33]. Increased rate of deep WM hyperintensities was consistently reported in BD [27]. Furthermore, reduced WM volumes were found in BD, even during first episodes [27, 29]. Importantly, widespread WM microstructure alterations (as mainly shown in dMRI data by decreased fractional anisotropy and increased radial diffusivity) were then robustly detected in BD [34–39]. The greater and most consistent WM changes in BD were found in the cingulum (especially anterior cingulum and regions close to the subgenual anterior cingulate cortex, and posterior cingulum) and corpus callosum (especially genu and body), as well as in frontal areas (especially orbitofrontal and subgenual regions), parahippocampal areas, and tracts such as the uncinate fasciculus and fornix, which mostly connect regions of the limbic system [34–39]. In our previous work, we found that widespread WM abnormalities were mainly detectable in patients recruited during the active phases of illness, while WM alterations localized in the anterior midline structures characterized all phases of BD [40]. Moreover, we observed the most consistent WM alterations, as well as deficits of structural connectivity in the anterior midline regions, in patients recruited during mania [26, 41]. Coherently with WM alterations shown in imaging studies, neuropathological data in BD revealed consistent reductions in number or density of oligodendrocytes, along with myelin abnormalities, in anterior brain regions especially [33, 42, 43].

Relationships between white matter and immunological alterations. In our prior work on BD, we firstly detected a specific correlation between WM alterations and the reduction in circulating terminal effector CD8+ T cells (especially in patients recruited during mania) [26]. Notably, such correlation was found only for terminal effector CD8+ T cells, which were reduced in the circulation and are effector cells prone to tissue migration, but not for other cells such as CD4+ T cells [26]. Moreover, WM alterations were also found to correlate with levels of cytokines such as TNFα and IFNγ in BD [44].

Considering all these data, some intriguing similarities as well as specific differences can be noted between BD and multiple sclerosis (MS), the prototype of immune-inflammatory demyelinating diseases of the central nervous system, with potential pathophysiological and psychopathological meanings [5, 26, 45, 46]. Beyond a robust epidemiological association [5, 15, 47–51], a similar immunological pattern can be observed between the two diseases, i.e., the increase in CD4+/CD8+ T cell ratio in the circulation, which is associated with accumulation of effector CD8+ T cells into brain's WM lesions in MS (suggesting that activated CD8+ T cells migrate into the brain where they recognize components of the myelin and contribute to WM damage as effector cells) [19, 26, 52–54]. Coherently, widespread damage in (normal appearing) WM has been reported in both disorders [38, 55, 56]. However, we observed that such WM alterations show a different spatial pattern, with a greater impairment in the anterior brain regions in BD and in the posterior brain regions in MS [57]. Coherently, we also showed that the occurrence of depressive symptomatology in MS was specifically

associated to WM alterations in a cluster mainly encompassing basal ganglia and thalamic areas (including the fornix) that are part of the limbic system, along with a related functional dysconnection of neurotransmitter-related brainstem nuclei [58]. These findings support the possibility of a partial mechanistic overlap in the immune-mediated WM damage between BD and MS, along with the potential role for a specific spatial pattern of WM alterations in the emergence of psychiatric symptomatology.

Collectively, these data may suggest that BD is associated with an immune response sustained by CD4+ T cells that lead to activation of CD8+ T cells and related inflammatory state, and such activated effector CD8+ T cells may migrate into brain tissue where their cytotoxic effects might contribute to widespread WM damage, which most consistently affects tracts connecting regions of the limbic system.

Limbic network alterations

The limbic network (LN) includes the subgenual anterior cingulate cortex and orbitofrontal cortex, along with their connections to the neurotransmitter-related brainstem nuclei, amygdala, hypothalamus, anterior thalamus, and hippocampus, and is involved in the stress-related modulation of homeostasis and neurotransmitter signaling [59–62]. Since the late 1990s, alterations in the LN have been investigated and consistently detected in depressive and bipolar disorders by Drevets, Ongur, Savitz, Mayberg, and other Authors [61, 63, 64]. Specifically, a localized decrement of GM volume was found in the subgenual anterior cingulate cortex and orbitofrontal cortex, which was associated with a reduction in glia without an equivalent loss in neurons, in BD [4, 65, 66]. Increased volume of the amygdala, along with volume reductions in the hippocampus, has been repeatedly detected in BD [4]. Moreover, structural network dysconnectivity (e.g., deficits in clustering and nodal efficiency) was consistently and specifically detected across such limbic regions (including orbitofrontal, cingulate, and hippocampal gyri) in BD [67, 68]. Finally, state-dependent changes in the metabolic activity of the subgenual anterior cingulate and orbitofrontal cortices, along with increased baseline metabolism in the amygdala and hyperactivity of the hypothalamus–pituitary–adrenal (HPA) axis (especially during mania), have been robustly associated with BD [4, 64, 69]. Importantly, the structural damage in the LN in BD seems to be related to metabolic overactivity [4]. Accordingly, inhibition of overactive limbic regions (e.g., inducing a metabolic decrease in the subgenual anterior cingulate cortex and related areas via chronic deep brain stimulation) was found to produce a clinical improvement of depressive symptomatology [64, 70].

Together, all these data might suggest that BD is characterized by an immune-mediated WM damage and its specific localization in the LN may play the core role in the pathophysiology of the disorder.

Stress response, inflammation, and changes in neurotransmitter signaling

Alterations of the LN in BD may have a complex role in the interplay between stress response, inflammation, and neurotransmitter dysregulation [5]. Stress-induced activity in the LN is associated with transient increases in dopamine (DA) and norepinephrine signaling, opioidergic signaling, and HPA axis activity, along with changes in serotonin (5HT) metabolism [71–73]. Moreover, stress response (both stress hormones, such as cortisol or norepinephrine, and sympathetic innervation) modulates immune cell activity, by acutely inducing a Th2 shift in the Th1/Th2 balance, while chronically causing low-grade inflammation characterized by increased pro-inflammatory factors such as IL-6, IFNγ, and TNF [5, 74, 75]. Interestingly, stress system activation can be associated with increased vulnerability to pathogens, especially viral diseases, e.g., a reactivation of latent herpesvirus can occur during stress responses [5]. Accordingly, an association between infection with cytomegalovirus (or also toxoplasma gondii) and depressive or bipolar disorders was reported [5]. Thus, viral reactivation, in presence of immune dysregulation, may contribute to inflammation and brain damage [76]. In turn, pro-inflammatory mediators are able to modulate neurotransmitter signaling [5, 77–79]. Specifically, pro-inflammatory cytokines, such as IFNγ, TNFα, and IL-6, enhance the activity of the indoleamine 2,3-dioxygenase (IDO) enzyme, which diverts tryptophan away from 5HT synthesis and favors the kynurenine pathway [5, 77–79]. This results in decreased availability of 5HT along with production (by activated microglia) of various metabolites, such as the quinolinic acid (able to activate NMDA receptors, potentially inducing excessive glutamate signaling and related excitotoxicity) and kynurenic acid (an NMDA receptor antagonist) [5, 77]. In turn, changes in frontal glutamatergic NMDA-mediated signaling may alter both DA and 5HT signaling (which are mainly reduced or increased by NMDA receptor agonists or antagonists, respectively) [80]. Furthermore, TNF and IL-1 induce the mitogen-activated protein kinases (MAPKs), which increase the expression and function of monoamine transporters, leading to decreased synaptic availability of neurotransmitters such as 5HT and DA [78]. Accordingly, inflammatory stimuli have been shown to induce a decrease in DA release in the basal ganglia, along with reduced activation of the ventral striatum and related emotional blunting, in both healthy and depressed individuals [78].

Coherently, increased levels of inflammatory markers, possibly along with related DA reductions, were associated with functional dysconnection between ventral striatum and ventromedial prefrontal cortex (correlating with anhedonia) and between dorsal striatum and supplementary motor area (correlating with psychomotor inhibition) in depressed patients [81]. However, it is worth noting that decreased availability of 5HT has been shown to induce a functional dysconnection of the 5HT-producing brainstem nuclei only in patients with affective disorders (and not in healthy subjects) [82].

Altogether, these data suggest that stress response and inflammation are physiologically able to induce changes in neurotransmitter availability, and this could pathologically affect the functional architecture of brain activity in BD, potentially in relation to structural alterations of the LN.

Intrinsic brain activity alterations

The functional architecture of intrinsic brain activity revealed various alterations in BD, as shown by resting-state functional MRI studies since the 2000s. Abnormalities in the subcortical–cortical functional connectivity (FC) have been associated with BD, as firstly reported by Anand et al. [83]. Moreover, increased FC between thalamus and sensorimotor cortical areas (along with decreased FC between thalamus and associative frontal cortices) was detected in BD by Anticevic et al. [84] and this finding has been consistently replicated [85–87]. At a network level, a functional dysconnectivity within the default-mode network (DMN) in BD was firstly detected by Ongur et al. in 2010 [88]. Subsequently, functional alterations were also reported in the other main networks, including sensorimotor network (SMN), salience network (SN), and central executive network (CEN), in BD (e.g., [89–93]). However, findings are heterogeneous, at times inconsistent, potentially also reflecting the clinical heterogeneity of BD. Accordingly, our group conducted a series of studies on BD investigating its different phases of illness separately (rather than considering BD overall), aiming to detect distinct brain alterations in mania and depression, which may reflect more closely the underlying pathophysiological features.

Neurotransmitter signaling alterations. In our prior work, we preliminary detected a functional dysconnection of neurotransmitter-related nuclei in BD, with distinct patterns in the different phases of illness [87]. The FC between 5HT-related raphe nuclei (RNi) and basal ganglia-thalamic regions was reduced in mania [87]. Additionally, the FC between DA-related substantia nigra (SNc) and basal ganglia-thalamic regions was reduced in depression (with psychomotor inhibition) [87]. These functional data complemented biochemical and behavioral findings on neurotransmitter signaling in mania and depression. Specifically, decreased 5HT transmission in BD, and in the manic phase especially, as well as decreased DA transmission in the depressive phase, have been reported as the most consistent neurotransmitter finding in BD [6, 94]. Coherently, deficits in 5HT activity have been associated with manic-like symptomatology (e.g., behavioral impulsivity), while deficits in DA activity with depressive-like symptomatology (e.g., motor inhibition) [95–99].

Subcortical–cortical loop alterations. In our previous work, we confirmed the thalamus-SMN hyperconnectivity in our BD sample and extended this finding by showing a distinct pattern of alterations in the active phases of illness [87]. Specifically, the thalamus-SMN FC increased by switching from mainly negative connectivity in healthy subjects to mainly positive connectivity in mania, reflecting an abnormal coupling between thalamus and SMN signals [87]. By contrast, the thalamus-SMN FC increased from mainly negative connectivity in healthy subjects to around-zero connectivity in depression (with inhibited psychomotricity), actually reflecting a decrease in the absolute strength of correlation (i.e., dissociation) between thalamus and SMN signals [87]. Moreover, the thalamus-SMN FC was unchanged in euthymia and, notably, was increased in agitated depression (similarly to mania rather than inhibited depression, suggesting a specific association between thalamus-SMN FC and psychomotor alterations) [87]. Additional subcortical–cortical FC alterations were found in the different BD phases by other Authors: increased FC between basal ganglia and thalamus, and between amygdala and SMN areas (along with decreased FC between amygdala and anterior cingulate cortex) was detected in mania, while increased FC between basal ganglia and SN areas was observed in depression [100–102].

Large-scale network alterations. In our prior work, we found altered topographical distribution in the neuronal variability (i.e., temporal variability of BOLD signal fluctuations, an indirect index of neuronal activity) across the cortex of BD patients, with opposite patterns in the active phases of illness [103]. Specifically, the ratio between neuronal variability in the SMN and DMN (in the ultra-low frequency band slow5 [104]) was increased in mania (i.e., the balance between SMN and DMN was tilted toward the SMN), and decreased in depression (i.e., the SMN/DMN balance was tilted toward the DMN), while no changes in this parameter were found in euthymia [103]. Moreover, we observed an abnormal global signal representation in BD, which was greater in SMN areas in mania while in DMN areas in depression [105]. We also showed reduced intra-network FC within the DMN in mania, while reduced FC within the SMN in depression [41, 90, 106]. Finally, we detected distinct alterations in regional homogeneity and degree of centrality (measures of local and global connectivity, respectively) in the BD phases: regional

homogeneity and degree of centrality (in the ultra-low frequency band slow4 [104]) were decreased in the DMN during mania (deficits of higher frequencies in the DMN were associated with their increase in SMN areas); conversely, regional homogeneity was decreased in the SMN during depression [106]. Notably, all these alterations in intrinsic brain activity coherently correlated with manic and depressive symptomatology in opposite way (interestingly, psychomotor hyperactivity positively correlated with SMN connectivity, while distractibility, which can be considered a deficit in internal thought, negatively correlated with DMN connectivity) [41, 90, 103, 105, 106]. Furthermore, network alterations were reported in the various BD phases by other Authors. Decreased FC within the DMN and increased FC within the dorsal attention network were detected during mania [88, 107]. Mania-inducing brain lesions were found to selectively disrupt functional connections of the associative areas, such as the dorsolateral prefrontal and temporal cortices, or the orbitofrontal cortex [108]. Network hyperconnectivity and greater clustering in the superior frontal gyrus (including the premotor cortex), amygdala, and midbrain (encompassing the DA-related SNc and ventral tegmental area, VTA) have been associated with manic symptomatology [109]. Conversely, decreased amplitude of low-frequency fluctuations in SMN areas (and increased in SN areas) were detected in depression [110]. Increased regional homogeneity was observed in DMN regions in depression [111]. Altered clustering and efficiency in the LN and DMN have been associated with depressive symptomatology [109, 112]. Finally, absence of network alterations was mainly reported during euthymia [113].

Together, these data show that mania might be associated with a functional dysconnection of the 5HT-related RNi, an increase in thalamus-SMN FC toward positive values, and a relative increase in SMN activity along with a decrease in DMN activity (coherently with the negative correlation of RNi-related FC with thalamus-SMN FC and SMN activity, as observed in healthy subjects) [87, 103, 114]. Conversely, depression might be associated with a functional dysconnection of the DA-related SNc, a decrease in thalamus-SMN FC toward around-zero values, and a relative decrease in SMN activity along with an increase in DMN activity (coherently with the positive correlation of SNc-related FC with the absolute value of thalamus-SMN FC and SMN activity, as observed in healthy subjects) [87, 103, 114]. Thus, such findings might suggest that the manic and depressive phases of BD are characterized by distinct functional reconfigurations of intrinsic brain activity, from changes in neurotransmitter signaling to abnormal subcortical–cortical coupling and alterations in network balancing.

Unified model of the pathophysiology of bipolar disorder

Based on the reported data, we propose a unified model of the pathophysiology of BD (Fig. 1).

Damage in the limbic network and alteration of neurotransmitter signaling

We hypothesize that the core pathological alteration in BD is an LN damage resulting in alterations of neurotransmitter signaling. Although heterogeneous conditions can lead to such damage, we suppose that the main pathophysiological mechanism is traceable to an immune-mediated WM damage involving the LN connections, which destabilizes the neurotransmitter signaling.

Immune dysregulation. A dysimmune response with a predominant pro-inflammatory profile occurs in BD [5]. According to the pathophysiological model of prototypical dysimmune diseases, environmental factors (e.g., microbial infections, physical or chemical agents) are supposed to trigger, on a susceptible polygenic background, a predominant and chronic pro-inflammatory activation (e.g., via molecular mimicry or bystander activation of pattern recognition receptors); it has been suggested that similar mechanisms also play a role in BD [5, 115].

White matter alterations. A widespread alteration of WM microstructure is associated with BD [37, 40]. The dysimmune response may lead to migration of immune effector cells, such as activated effector T cells, into brain tissue (along with activation of microglia and increase in pro-inflammatory mediators) and consequent cytotoxic activity on oligodendrocytes and myelin may result in widespread WM damage (similarly to what observed in MS) [5, 26, 54, 56, 57].

Immune-mediated white matter damage in the limbic network and destabilization of neurotransmitter signaling. A concomitant stress-related limbic overactivity is associated with BD [4, 5, 64]. This could play a role in the resulting spatial pattern of the immune-mediated WM damage, as characterized by greater involvement of the LN [37, 40, 41, 57]. Hypothetically, an LN hypermetabolism may divert the cerebral blood flow, along with the pro-inflammatory cells/mediators, onto its hyperactive regions. This may result in a (immune-mediated) structural alteration in such (stress-related) LN, mainly encompassing the subgenual anterior cingulate cortex, orbitofrontal cortex, and their reciprocal connections with the subcortical areas and neurotransmitter-related brainstem nuclei [4, 61, 62]. Thus, such structural alterations in the connections of LN may result in correspondent functional alterations of the neurotransmitter-related nuclei [58], destabilizing the neurotransmitter signaling

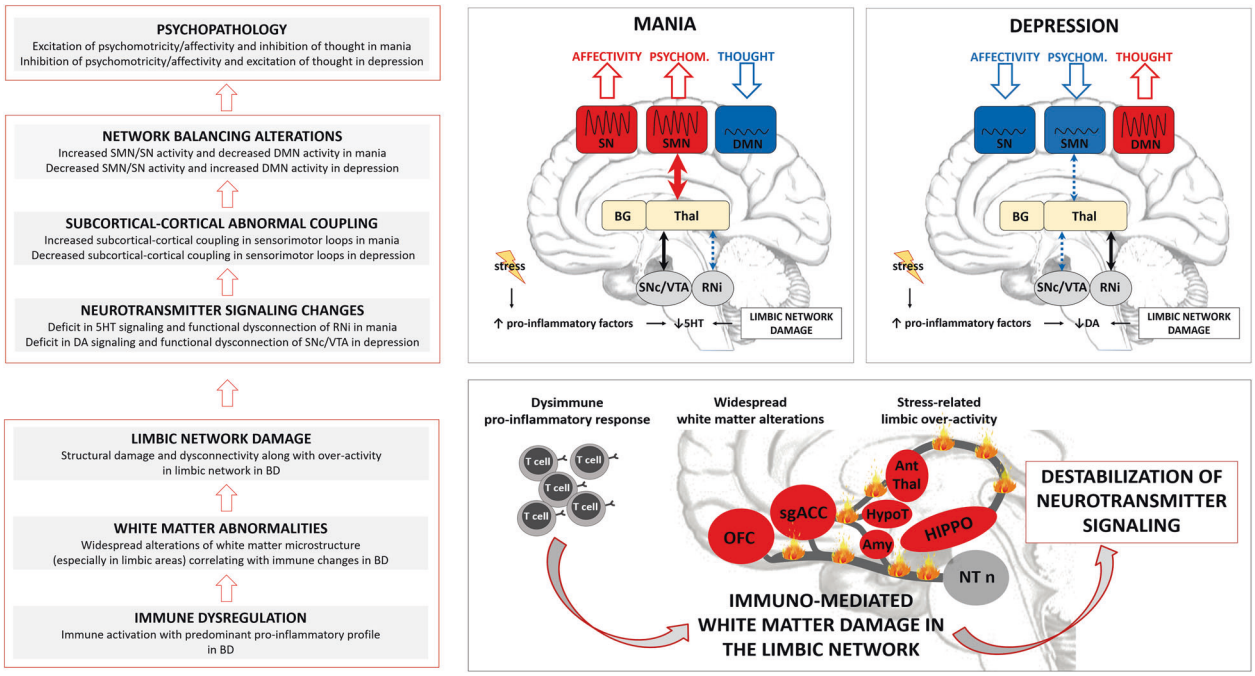

Fig. 1 Unified model of the pathophysiology of bipolar disorder. *Damage in the limbic network and alteration of neurotransmitter signaling (lower part).* According to the model, the core pathophysiological mechanism in BD could be traceable to an immune-mediated white matter alteration resulting in a limbic network damage, which destabilizes the neurotransmitter signaling increasing its susceptibility to perturbations. *Functional reconfiguration of intrinsic brain activity and psychopathology (upper part).* Changes in neurotransmitter signaling (triggered by heterogeneous stressors and inflammatory states onto a damaged limbic network) may then lead to phasic reconfigurations of intrinsic brain activity, from abnormal subcortical–cortical coupling to changes in network balancing. Finally, this may clinically manifest in the psychopathological alterations of mania and depression. *Abbreviations*: BD bipolar disorder, OFC orbitofrontal cortex, sgACC subgenual anterior cingulate cortex, Amy amygdala, HypoT hypothalamus, Ant Thal anterior nuclei of thalamus, HIPPO hippocampus, NT n neurotransmitter-related nuclei, DA dopamine, 5HT serotonin, SNc/VTA substantia nigra/ventral tegmental area, RNi raphe nuclei, BG basal ganglia, Thal thalamus, SN salience network, SMN sensorimotor network, DMN default-mode network.

and increasing its susceptibility to perturbations by various stressors from the external or internal environment.

Functional reconfiguration of intrinsic brain activity and psychopathology

In accordance with our recently proposed three-dimensional model of brain functioning and behavioral/phenomenological patterns [9], we then suggest that changes in neurotransmitter signaling (potentially triggered by heterogeneous environmental stressors onto a structurally-damaged LN) lead to phasic (and often recurrent) reconfigurations of intrinsic brain activity. This might represent a pathological re-setting of the pre-existing baseline in intrinsic brain functioning (and related temperamental features), resulting in distinct changes in network balancing that alter the basal pattern of input/output processing. Finally, this may clinically manifest in the complex psychopathology of manic and depressive states of BD. See Supplementary Material and our previous work [9].

Stress response, inflammation, and changes in neurotransmitter signaling. The occurrence of a stress response, which is facilitated by a hyper-(re)active stress system and able to trigger the active episodes of BD, can cause a prolonged increase in pro-inflammatory factors, such as IL-6, IFNγ, and TNF (e.g., a stress-related Th2 shift in the Th1/Th2 balance may favor a reactivation of latent infection of viruses, like herpesviruses, with related pro-inflammatory rebound) [5, 74]. This, in turn, can induce a reduction of 5HT availability (e.g., via IDO activity and kynurenine pathway enhancement) and/or DA availability (e.g., via MAPK activity enhancement) [5, 77, 78]. A decrease of neurotransmitter availability in a structurally-damaged LN may then lead to a functional dysconnection of the neurotransmitter-related nuclei, finally resulting in functional reconfigurations of intrinsic brain activity.

Changes in neurotransmitter signaling, functional reconfigurations of intrinsic brain activity, and psychopathological states. A reduction of 5HT availability may lead to RNi dysconnection (e.g., [87]). This may result in an abnormal neuronal coupling in the sensorimotor subcortical–cortical loops (e.g., [87]). In turn, this may lead to increased levels of intrinsic activity within the SMN and SN at the expense of the DMN (and related shift toward slow4) (e.g.,

[41, 88, 90, 103, 105–108]). This may over-tune the intrinsic brain activity onto the current environment and clinically manifest in a manic state with excited psychomotricity and affectivity as well as inhibited thought [9]. Conversely, a reduction of DA availability may lead to SNc/VTA dysconnection (e.g., [87]). This may result in a neuronal decoupling in the sensorimotor subcortical–cortical loops (e.g., [87]). In turn, this may lead to decreased levels of intrinsic activity within the SMN and SN with relative increase in the DMN (and related shift toward slow5) (e.g., [103, 105, 106, 110, 111]). This may de-tune the intrinsic brain activity from the current environment and clinically manifest in a depressive state with inhibited psychomotricity and affectivity as well as excited thought [9]. Furthermore, other combinations of changes in neurotransmitter signaling may also occur, resulting in other specific reconfigurations of intrinsic brain activity and related psychopathological states [9, 116]. See Supplementary Material.

Additional pathophysiological factors and clinical–biological subgroups of illness

Finally, we suppose that additional pathophysiological factors may result in clinical–biological subgroups of BD. According to our model, the typical form of BD is primarily characterized by immune-inflammatory factors and related WM damage mainly encompassing the LN. Consequent phasic reconfigurations of intrinsic brain activity might superimpose onto structurally-preserved GM, manifesting in the psychopathological alterations during the active episodes and remission during euthymia. The extent of LN damage could be related to episode recurrence (with lesser or greater LN damage in the occurrence of one/few or multiple episodes, respectively). This may result in the phasic-recurrent course of illness. On the other hand, we suggest that a subgroup of BD might be characterized by additional neurodevelopmental and/or neurodegenerative factors (e.g., alterations in synaptic plasticity) that result in GM loss [4, 31]. Thus, the reconfigurations of intrinsic brain activity might superimpose onto structurally-damaged GM, so that the psychopathological alterations during the active episodes might be associated with impoverished contents of thinking and behavior that persist even during euthymia. The extent of GM damage could be related to cognitive deterioration (with lesser or greater GM damage in the secondary presentation (after recurrent episodes) or primary presentation (since the first episode) of cognitive deterioration, respectively). This may result in a tendency to a progressive course of illness. Thus, such distinct clinical–biological subgroups of BD with predominant relapsing-remitting or progressive patterns (partially mirroring the subtypes of MS) [54, 117] might be related to a predominant contribution of immune-inflammatory or neurodevelopmental/neurodegenerative pathophysiological factors.

See Supplementary Material for a discussion of various critical issues (e.g., [118–120]) and future directions.

Conclusions

Our unified model might provide a framework for integrating the current data on BD and suggest novel specific hypotheses that can be tested in future investigations, prompting for a better understanding of the pathophysiology of BD. In turn, this could provide novel diagnostic markers and therapeutic targets, opening the door to potential new strategies of therapy.

Plasticity in the Frequency Representation of Primary Auditory Cortex following Discrimination Training in Adult Owl Monkeys

G. H. Recanzone,[1] C. E. Schreiner, and M. M. Merzenich

Coleman Laboratory, Departments of Otolaryngology and Physiology and Keck Center for Integrative Neuroscience, University of California at San Francisco, San Francisco, California 94143-0732

Previous studies have shown that the tonotopic organization of primary auditory cortex is altered subsequent to restricted cochlear lesions (Robertson and Irvine, 1989) and that the topographic reorganization of the primary somatosensory cortex is correlated with changes in the perceptual acuity of the animal (Recanzone et al., 1992a–d). Here we report an increase in the cortical area of representation of a restricted frequency range in primary auditory cortex of adult owl monkeys that is correlated with the animal's performance at a frequency discrimination task.

Monkeys trained for several weeks to discriminate small differences in the frequency of sequentially presented tonal stimuli revealed a progressive improvement in performance with training. At the end of the training period, the tonotopic organization of AI was defined by recording multiple-unit responses at 70–258 cortical locations. These responses were compared to those derived from three normal monkeys and from two monkeys that received the same auditory stimuli but that were engaged in a tactile discrimination task. The cortical representation, the sharpness of tuning, and the latency of the response were greater for the behaviorally relevant frequencies of trained monkeys when compared to the same frequencies of control monkeys. The cortical area of representation was the only studied parameter that was correlated with behavioral performance. These results demonstrate that attended natural stimulation can modify the tonotopic organization of AI in the adult primate, and that this alteration is correlated with changes in perceptual acuity.

[Key words: auditory cortex, primate, plasticity, behavior, physiology, discrimination training]

Studies within the somatosensory system have shown that partial peripheral dennervation and restricted natural stimulation can result in a reorganization of the topographic representation of the body surface in the cerebral cortex (see Merzenich et al., 1990; Recanzone and Merzenich, 1992). Similarly, reorganization of the topographic representation of the cochlea in the primary auditory cortex has been demonstrated following partial cochlear lesions (Robertson and Irvine, 1989; Irvine et al., 1991). Tuning properties of single cortical neurons have been shown to be altered by conditioning paradigms (Olds et al., 1972; Disterhoft and Stuart, 1976; Kitzes et al., 1978; Ryugo and Weinberger, 1978) and pharmacological manipulations (Ashe et al., 1989; McKenna et al., 1989; Metherate and Weinberger, 1990; see Weinberger et al., 1990, for review). Although the cortical tonotopic map was not explicitly studied, the functional plasticity at the single neuron level suggests that the tonotopic representation of the cochlea in the cortex may be altered as a result of the behavioral training.

Reorganization of cortical representations has been argued to be continuous throughout life and to reflect an individual's ability to acquire new skills and behaviors (Merzenich et al., 1988, 1990). Improvements in performance have been demonstrated for both simple auditory detection and discrimination tasks (Zwislocki et al., 1958; Sinnott et al., 1985; Prosen et al., 1990), and similar improvements in performance on tactually based tasks have recently been demonstrated to parallel changes in the functional organization of somatosensory cortical areas 3a and 3b (Recanzone et al., 1992a–d). The demonstrations that auditory cortical neurons can alter their frequency-specific response properties by either peripheral dennervation or behavioral conditioning suggested to us that the types of cortical reorganization seen in the somatosensory cortex also occur in primary auditory cortex. Specifically, we hypothesized that the functional organization of AI is altered as a consequence of an animal's improvement in auditory discrimination ability. To test this hypothesis, three adult owl monkeys were trained at an auditory frequency discrimination task for several weeks. The tonotopic representation of the primary auditory cortex was defined electrophysiologically after significant improvements in performance were measured. The response properties of these neurons were then compared to those of normal monkeys, as well as to those of monkeys that had received the same auditory stimulation but were engaged in an unrelated tactile task. The electrophysiological data were then analyzed to determine if any simple measure of the cortical representation of the frequencies used in the behavioral paradigm was correlated with the improved behavioral performance.

Materials and Methods

Animals. Ten adult owl monkeys of both sexes were used. Animals were judged to have normal hearing based on evoked potential recordings (ABR). The outer ear canal was determined to be free of obstruction and infection. Monkeys were given free access to water and were food deprived for a 21–22 hr period prior to each psychophysical testing session. Supplemental fruit was given at the end of each testing session to maintain body weight between 85–95% ad lib. The care and treatment

of these monkeys were in accordance with the NIH Guide for the Care and Use of Laboratory Animals (revised 1987).

Psychophysics. The psychophysical apparatus and methods have been described in detail (Recanzone et al., 1991). Five monkeys were trained to detect a difference in the frequency of sequentially presented pairs of tone pips. Monkeys were trained in an acoustically transparent test cage housed within a single-walled acoustic chamber lined with echo-attenuating foam. Auditory stimuli were delivered in the free-field from a single speaker (Realistic model 14-1996) located directly over the animal's head. All aspects of the stimulus generation and data collection were automated and under the control of a microcomputer.

Monkeys were trained to initiate a trial by contacting a hand mold (monkeys OM1, OM2, OM3, CM1) or bar located outside of the test cage (OM4 and OM5), or by pulling a lever located inside the test cage (CM2). In each case, this observing response located the animal's head in a stereotyped location and orientation. Head position was monitored continuously with a video camera. Tone pip pairs were presented every 650 msec. Each tone pip had a duration of 150 msec (3 msec rise/fall), with the onset of the second pip occurring 50 msec after the offset of the first. The frequency of the first tone pip was constant for a given frequency discrimination task. Four different frequency ranges were tested: 2.5 kHz task (2511 Hz standard), 3 kHz task (3188 Hz standard), 5 kHz task (4765 Hz standard), and 8 kHz task (7950 Hz standard). Each monkey was extensively trained on at least one of these four tasks, and most were also tested on at least one other task on a few sessions spaced throughout the training period. The comparison, or S1, stimulus consisted of both tone pips of the pair being equal in frequency (the standard). For the target, or S2, stimulus, the frequency of the second tone pip was different from the frequency of the standard. Monkeys were required to maintain contact with the mold, bar, or lever throughout the presentations of the S1 stimuli, and to release contact upon detection of the S2 stimulus within a 450 msec reward window beginning 100 msec after S2 stimulus onset. Failures to release within this reward window were scored as a "miss" and were punished by a 1–5 sec time-out. Releases before this time were scored as a "false-positive" and also resulted in a time-out. Releases within the reward window were scored as a "hit" and the monkey received a 45 mg banana-flavored food pellet (Bio Serve). Six to ten different S2 stimulus frequencies were presented on at least 20 trials during a given session. These frequencies were chosen such that the monkey received a reward on 65–75% of all trials. Each monkey would perform 400–750 trials in a daily session.

The number of S1 stimulus presentations (bins) on a given trial was pseudorandomly determined to be between 2 and 11. The probability that the next stimulus would be an S2 (approximately 0.3) did not vary during the course of a single trial. In the condition that 11 S1 stimuli were presented, the 12th stimulus was always the S2. These trials were not included in the data analysis, as they were predictably the S2 based on time alone. Trials in which the monkey made a response in bins 1 and 2 were similarly omitted as they were always the S1. The performance (P) for each S2 frequency was defined by

$$P = H \cdot S,$$

where H is the hit rate for that frequency (H = # correct responses/# presentations) and S is the safe rate correction factor (S = 1 − false-positive rate). The psychometric function for each session was determined by plotting P as a function of the frequency difference between the S1 and S2 stimuli (delta frequency: ΔF). Threshold was defined from this function as the S2 frequency at which $P = 0.50$. This is a reliable measure for discrimination performance that is essentially unaffected by false-positive rates below 15% (see Recanzone et al., 1991, 1992a). The slope of the psychometric function was defined as the slope of the line connecting the data points immediately above and below threshold. Threshold was defined in all sessions in which at least one S2 stimulus had a performance value below 0.50 and the false-positive rate for the session was below 15%. The psychophysical data for several different S2 frequencies were subjected to signal detection analysis as described by Green and Swets (1966) for five consecutive training sessions spaced throughout the total training period (see Results). This analysis measures the difference in the response between the S1 and S2 stimuli in units of standard deviation and is independent of changes in the subject's internal criteria.

Three classes of control trials vertified that responses were based on the perception of the frequency of the auditory stimulus. On approximately 2% of the trials, the S2 stimulus was not presented until after 11 S1 presentations (described above). On these trials, a release response after the 12th stimulus always resulted in a reward; however, the performance at any given frequency was comparable regardless of the stimulus presentation bin. On 0.5–1.0% of the trials, the S2 stimulus generated by the computer had a delta frequency of zero (S1 = S2). Monkeys under stimulus control never responded in this condition. Finally, monkeys did not respond on trials in which the speaker was disconnected yet all other aspects of the trials were identical.

In order to prevent intensity cues as a function of frequency consequent to changes in the location of standing waves present in the free field, the intensity of each tone pip was varied independently over a 10–12 dB range. The intensity of the stimuli centered in this range was measured at three or four different frequencies at 12 separate locations throughout the sound field for each of the four tasks (Table 1). These locations were chosen to sample the area occupied by the monkey's head during a session and formed a cube of approximately 5 cm/side, with four additional measurements within this cube. There was no statistically significant difference in the intensity measured throughout the sound field between any of the four tested frequencies for each task (two-tailed t test; $p > 0.10$). Furthermore, repeated measures throughout the course of this study showed no statistical differences over time. The spectral content of these signals was measured in the free field to determine the potential contributions of each harmonic of the signal. The highest-intensity harmonics were always 40–50 dB less than the intensity of the fundamental. Finally, the head position of each monkey was viewed continuously with a video camera on each session, and analysis of head position with the behavioral response was made from several videotaped sessions in each monkey. This analysis showed no consistent relationship between the location or small movements of the monkey's head with the presentation of stimuli or with the behavioral response.

In addition to the five monkeys trained at the auditory frequency discrimination task, one monkey (CM1) was trained to detect a change in the frequency of a sinusoidal tactile stimulus (monkey E-2 of Recanzone et al., 1992a–d). The same auditory stimuli as used in the 8 kHz task were presented simultaneous to the presentation of the tactile stimulus, but did not give any indication of reward availability. Monkey CM2 was trained to perform a tactile vibration detection task in the presence of the same auditory stimuli used in the 5 kHz task. These monkeys represent passive-stimulation controls.

Electrophysiology. The primary auditory cortex was defined electrophysiologically in the seven monkeys trained in a psychophysical task and in three normal owl monkeys (N1, N2, and N3) that had not been trained at any task. Anesthesia was induced with a halothane (3%) : nitrous oxide (72%) : oxygen (25%) gaseous mixture. The femoral vein was cannulated and sodium pentobarbital was given intravenously to maintain an areflexic state of anesthesia (28 mg/kg induction, 1–5 mg/hr maintenance). Penicillin G (30,000 U/24 hr) and atropine sulfate (0.1 mg/kg/12 hr) were given intramuscularly. Lactated Ringer's solution with 5% dextrose was continuously infused (2–5 ml/hr). Heart rate, respiration rate, and other vital signs were monitored. Core body temperature was maintained at 37°C with a thermostatically controlled heating blanket. A craniotomy exposed the relevant cortical region, the dura was removed, and a well of silicon oil was constructed to bathe the cerebral cortex continuously. A 40× image of the cortical surface was taken either photographically or with a digitized video image. All electrode penetrations were parallel to each other. The electrode insertion points were reproduced onto the image of the cortical surface with reference to the vasculature. Electrode penetrations away from the sulcus were made only to a single depth corresponding to the middle cortical layers (500–900 μm below the cortical surface).

The stimulus generation and data acquisition methods have been described in detail elsewhere (Schreiner and Mendelson, 1990). Briefly, single tone pips of 50 msec duration (3 msec on/off ramp) were generated by a microprocessor (TMS32010, 16 bit D/A converter at 120 kHz, low pass filtered at 35 kHz) and presented monaurally via a calibrated headphone (STAX 54) connected to a sound delivery tube sealed into the contralateral ear canal. Characteristic frequency (CF) and threshold were defined audiovisually at all recording locations in all monkeys. Frequency–response areas (FRAs) were defined for all locations in monkeys OM1, OM3, and CM1, and in all three normal monkeys. FRAs were reconstructed from the response to a single stimulus at each of 45 frequencies spanning a 2–5 octave range centered at the approximate characteristic frequency (CF) and equidistant on a logarithmic scale. Each frequency was presented at each of 15 levels spanning a 70 dB range in 5 dB steps (675 total stimuli). Q10dB and Q40dB were defined from these frequency response areas as the CF divided by the bandwidth

Table 1. Mean and SD of sound intensities (dB SPL) measured at 12 locations within the sound field of the apparatus

Task	S1 stimulus	Below threshold	Near threshold	Above threshold
2.5 kHz	64.27 ± 2.7	64.44 ± 2.89	64.17 ± 2.93	65.27 ± 2.93
3 kHz	57.65 ± 3.97	59.55 ± 3.01	60.16 ± 2.90	57.15 ± 3.78
5 kHz	54.72 ± 2.93	55.39 ± 3.08	56.51 ± 3.47	53.55 ± 3.88
8 kHz	71.60 ± 4.69	71.81 ± 4.35		73.13 ± 4.71

Measurements were taken at the mid-range intensity used in the behavioral task. In the 2.5 kHz, 3 kHz, 5 kHz, and 8 kHz tasks, the frequencies measured under "S1 stimulus" were 2511 Hz, 3188 Hz, 4765 Hz, and 7950 Hz; "Below threshold" were 2527 Hz, 3275 Hz, 4849 Hz, and 8036 Hz; "Near threshold" were 2534 Hz, 3367 Hz, 4939 Hz; and "Above threshold" were 2613 Hz, 3641 Hz, 5212 Hz, and 8371 Hz, respectively.

10 dB and 40 dB above minimum threshold, respectively, following methods described by Schreiner and Mendelson (1990) and Sutter and Schreiner (1991). The minimum latency was defined as the time from stimulus onset to the earliest consistent response for all 15 intensity levels presented for the three frequencies nearest CF (45 stimuli total).

Electrodes were parylene-insulated tungsten wires with impedances of approximately 1 MΩ at 1 kHz (Microprobe, Inc). Neural signals were amplified, band-pass filtered (1–10 kHz), and displayed on an oscilloscope and audio amplifier. Spike activity was isolated from this signal with a window discriminator (BAK DIS-1) set to accept all waveforms greater than two times the neural noise level with the time window set for the peak of the largest responses. This eliminated evoked potentials and included approximately one to five independent waveforms of neural origin. The number and arrival time of each event relative to stimulus onset were recorded and stored in a computer (DEC 11/73).

At the start of each experiment, the angle of the electrode was set to be approximately parallel with the angle of the sulcus. Our objective was to define tuning curves limited to neurons in the middle cortical layers, which characteristically have the "best" responses as defined by vigorous activity with a short latency and well-defined tuning curves. Three long penetrations were made approximately 300 μm apart and located along a line perpendicular to the sulcus. In these penetrations, the neural response to acoustic stimuli was defined audiovisually in 500 μm steps. By comparing the neural responses at equivalent distances along these three tracks, we were able to verify that the angle of the penetration was roughly parallel to the sulcus. Electrode tracks near the sulcus were continued until an unambiguous border with another cortical field (marked by an abrupt shift in characteristic frequency) was encountered, or until neural activity could no longer be evoked with acoustic stimuli. These penetrations were commonly 3–4.5 mm in length.

At the conclusion of the electrophysiology experiments, electrolytic lesions were made at selected locations by passing 10 μA of direct current for 10–20 sec. Carbon particle marks were made by insertion of a tungsten electrode that had been coated with india ink at four to seven locations surrounding the investigated cortical tissue. The animals were given a lethal injection of barbiturate, and then perfused intracardially with normal saline at 37°C followed by one of two fixatives in phosphate buffer: 10% formalin or 1.5% paraformaldehyde with 1.5% glutaraldehyde. Frozen sections were cut at 100 μm thickness in the frontal plane. The sections were parallel to the electrode penetrations as indicated by the carbon particle marks. Alternate sections were stained with cresyl violet or for endogenous cytochrome oxidase activity (Wong-Riley et al., 1978). The angle of the electrode penetrations and the distances between recording locations were reconstructed with reference to the electrolytic lesions and carbon particle marks. AI maps represent reconstructions of all recording locations that corresponded to the middle cortical layers III and IV, approximately 500–900 μm below the pial surface. These maps are presented in two dimensions by projecting the location of the recording site along the radial direction to a point where it intersected an imaginary line drawn 700 μm below the cortical surface. This technique limits the distortion that results from projecting recording sites to the surface of the crown of the sulcus. Results from recording locations in other cortical layers are not reported here.

Cortical areas of representation were measured by defining borders as equidistant between neighboring recording locations. The approximate error in these area measurements at interpenetration distances used in these experiments is on the order of 10–20% (see Merzenich et al., 1987; Recanzone et al., 1992b). Statistical analysis of all behavioral and electrophysiological data was done using the software STATVIEW 512+. The specific statistical test was an unpaired one-tailed t test unless otherwise indicated. p values ≤ 0.05 were considered to be statistically significant.

Results

Psychophysics

Improvement in performance with training. The auditory frequency discrimination abilities of each of the five trained monkeys improved progressively with training. The improvement in threshold with training is shown for two representation monkeys in Figure 1. This improvement was characterized by a relatively short and steep phase in which large improvements were recorded between sessions, followed by a longer period in which smaller gains were observed. These observations are summarized for each of the five monkeys in Figure 2. The discrimination threshold was averaged over five sessions at different periods roughly equally spaced throughout the several week training period. In almost every case, the largest gains were measured between the initial five sessions and the five sessions taken after approximately one-third of the total number of sessions. The decrease in threshold was generally less throughout the remainder of training, although significant decreases were measured in every monkey ($p < 0.05$). Final mean discrimination thresholds were slightly better for the 2.5 kHz task than the 8 kHz task (see Table 2). By contrast, the final thresholds for the 5 kHz and the 3 kHz tasks in monkeys OM4 and OM5 were much greater, even though these monkeys also showed significant improvements with training.

Previous studies in owl monkeys on tactile frequency discrimination performance have shown that improvements in minimally detectable frequency differences resulted from (1) a leftward shift in the psychometric function and (2) an increase in the slope of the psychometric function (Recanzone et al., 1992a). Representative psychometric functions from one session within each of the four periods of auditory training shown in Figure 2 are reproduced for monkeys OM1 (*A*) and OM3 (*B*) in Figure 3. Consistent with the results from the tactile task, the performance at each S2 frequency increased in a roughly sequential fashion, with the performance at large frequency differences improving before the performance at smaller frequency differences. For example, delta frequencies (ΔF values) above 300 Hz for OM1 had improved to near maximum performance by session 36, whereas the performance at the ΔF of 80 Hz did not begin to improve until after this session. Similar examples could be cited for each monkey.

The slope of the psychometric function also increased throughout the training period. The average slopes of the psychometric function at threshold over five sessions are shown

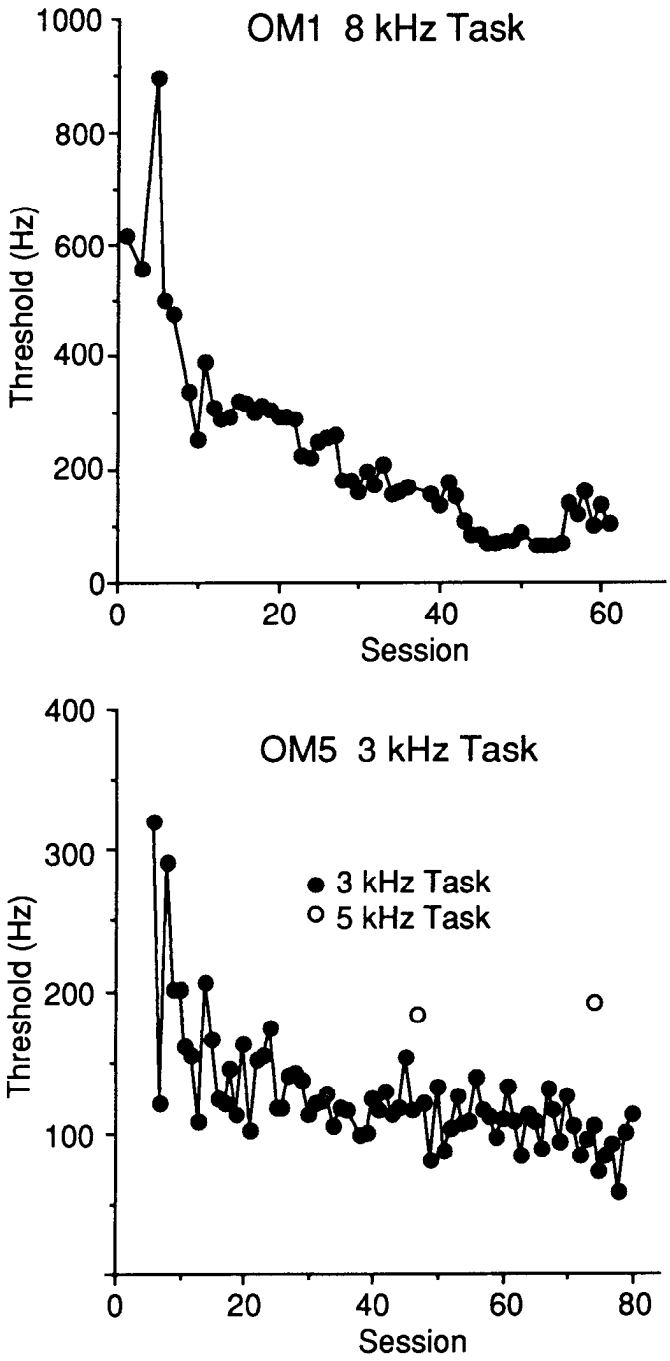

Figure 1. Progressive improvement in the frequency discrimination threshold measured on daily sessions. The delta frequency with a performance of 0.50 is plotted for all sessions in which at least one S2 frequency had a performance below 0.50 (minimum 20 presentations), and the overall false-positive rate was below 15%. *Solid circles* denote the frequency range tested on repeated sessions (8 kHz and 3 kHz for *A* and *B*, respectively), and *open circles* represent sessions using an untrained frequency range (5 kHz in *B*).

for each monkey in Figure 4 for the same training periods as shown in Figure 2. These slopes increased significantly between at least two of the training periods measured, and between the slopes measured in the initial and final training sessions for all monkeys except OM5, which did not reach statistical significance ($p = 0.091$). Thus, consistent with observations in the tactile frequency discrimination task, the improvement in performance was marked by a roughly sequential increase in the

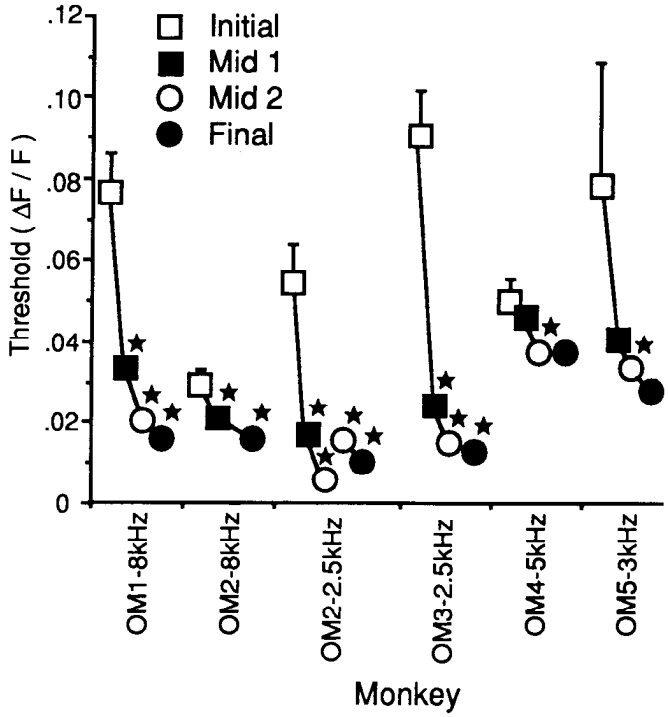

Figure 2. Decrease in frequency discrimination threshold with training. The discrimination thresholds taken over five continuous sessions are shown (mean and SE) for each monkey trained at the auditory frequency discrimination task. Units are given in $\Delta F/F$. *Initial* sessions are taken as sessions 1–5; *Final* sessions are the five sessions immediately preceding the electrophysiology experiment. *Mid 1* and *Mid 2* were chosen to divide the total training period into four roughly equal periods. Error bars not drawn were smaller than the symbol size. *Stars* indicate statistically significant differences between the *starred symbol* and the immediately preceding training period. *OM2-2.5 kHz* is shown in two periods because training at the 2.5 kHz task was interrupted by training on the 8 kHz task (see Fig. 6). Sessions shown for this monkey are 1–5, 30–34, 57–61, 88–92, and 107–111.

performance at each S2 frequency and an increase in the slope of the psychometric function at threshold.

One way in which decreases in threshold could occur is by a shift in the monkey's internal criteria by which it makes a re-

Table 2. Final thresholds measured for all behaviorally trained monkeys

Task	Monkey	# Sessions	$\Delta F/F$
2.5 kHz	OM2	61/24	0.005/0.010
2.5 kHz	OM3	97	0.013
3 kHz	OM5	80	0.028
3 kHz	OM4	6	0.045
5 kHz	OM4	75	0.038
5 kHz	OM5	2	0.040
8 kHz	OM1	61	0.015
8 kHz	OM2	26	0.016
8 kHz	OM3	4	0.041
Passive, 8 kHz	CM1	131	—
Passive, 5 kHz	CM2	75	—

Threshold measurements represent the mean of the final five sessions for trained tasks, or all sessions for tasks with six or less total training sessions. The two measurements for OM2 represent the two training periods for the 2.5 kHz task that bracketed the training at the 8 kHz task. No auditory thresholds were derived in the passive-stimulation animals.

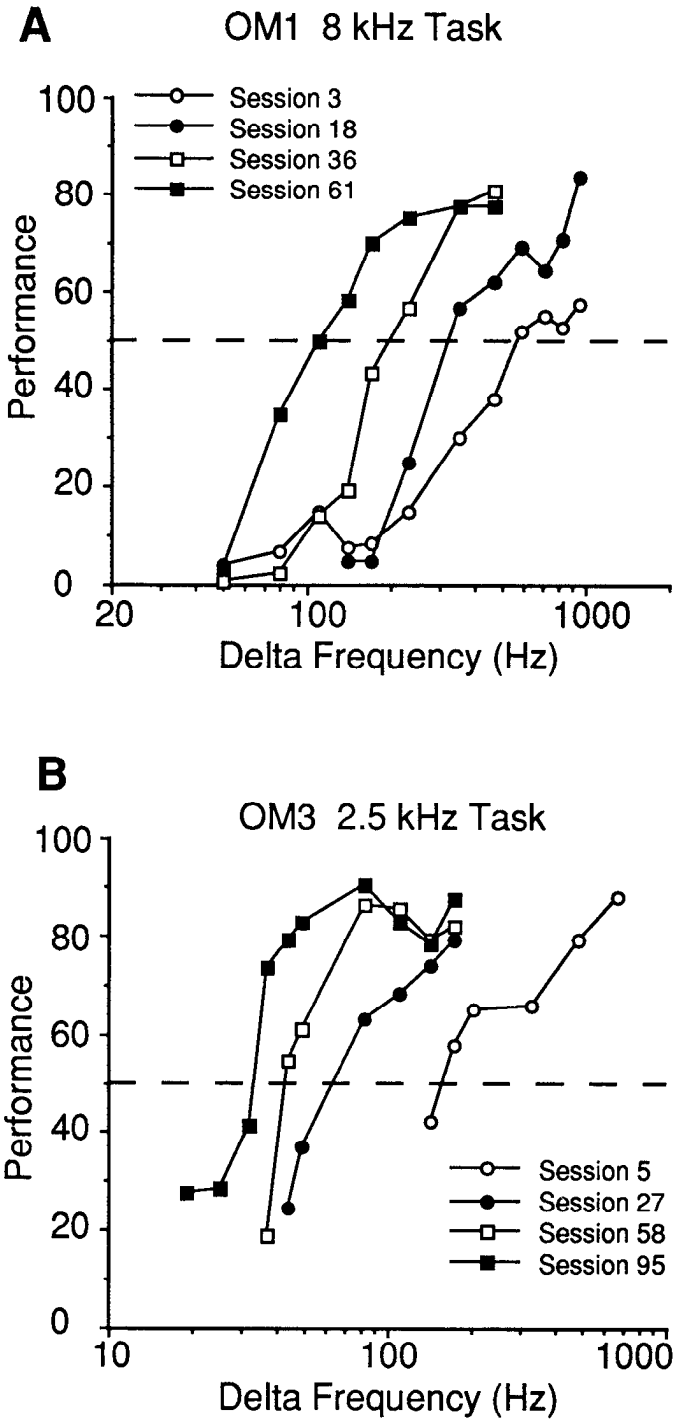

Figure 3. Representative examples of psychometric functions taken during the training periods (see Fig. 2). The *broken line* defines threshold (50% performance). Psychometric functions shifted to smaller frequency differences and appeared to become steeper during the course of training in all studied monkeys.

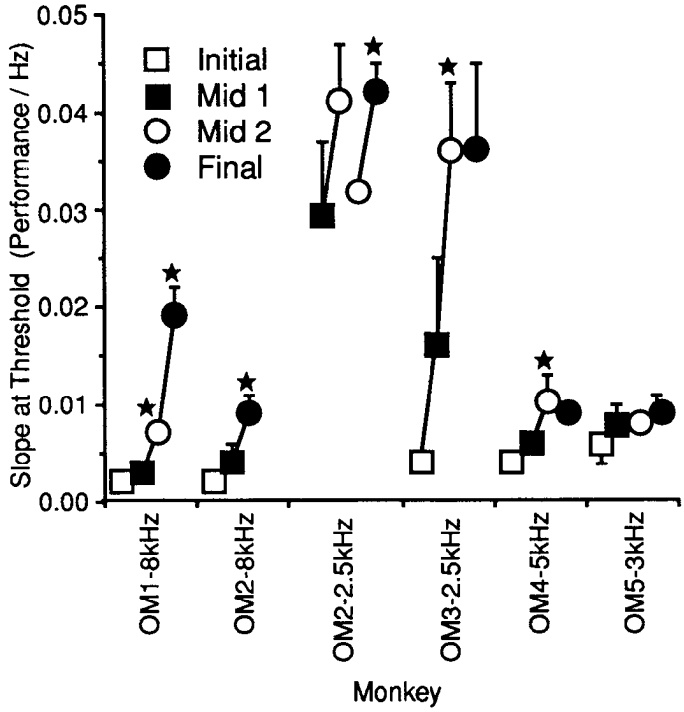

Figure 4. Slope of the psychometric function at threshold in all trained monkeys. The mean and SE of the slope of the psychometric function at threshold are shown for the four training periods as defined in Figure 2 for all monkeys. *Stars* indicate statistically significant differences.

sponse (see Green and Swets, 1966; Recanzone et al., 1992a). The increased slope of the psychometric functions argues against this explanation. A second line of evidence is that the false-positive rate was maintained below 15% and did not significantly change over the course of training. Furthermore, there was no significant correlation between the false-positive rate and the hit rate measured for any ΔF near threshold (hit rates of 20–90%) in any of the five owl monkeys studied ($p > 0.05$ in all cases). Finally, the measure of d' for at least three S2 frequencies was analyzed over the four training periods for each monkey. In every monkey there was at least one statistically significant increase in the measure of d' between training periods for each frequency tested (and no significant decreases). The results from the two monkeys that had the highest discrimination thresholds are shown in Figure 5. Even in these monkeys, there was a sequential increase in the measure of d' with training. These results indicate that the improvements in performance as reflected in the measures of threshold and d' reflect a true increase in perceptual acuity with training.

Transference. Previous studies had indicated that training one sensory surface in a perceptual task confers limited gains in that task to nearby sensory surfaces (see James, 1890; Craig, 1988; Recanzone et al., 1992a). In each monkey excluding OM1, the performance at one other frequency range was tested at various times throughout the training period (Table 2). The most extensively studied animal was OM2, which was trained initially on the 2.5 kHz task, was then shifted to the 8 kHz task, and was finally returned to the 2.5 kHz task (Fig. 6). The characteristic decrease in threshold was observed for both the 2.5 kHz task (solid circles) and the 8 kHz task (open circles). The thresholds measured on the 2.5 kHz task increased during the course of training at the 8 kHz task. The thresholds then decreased again when the task was shifted back to 2.5 kHz. A second feature to note is that the 8 kHz task does not show a rapid improvement in performance at the initial period of training (compare Fig. 6 with Fig. 1, and see Fig. 2).

If a particular frequency outside the normal training range was tested on two or three individual sessions that were widely spaced in time, there was no improvement in performance for

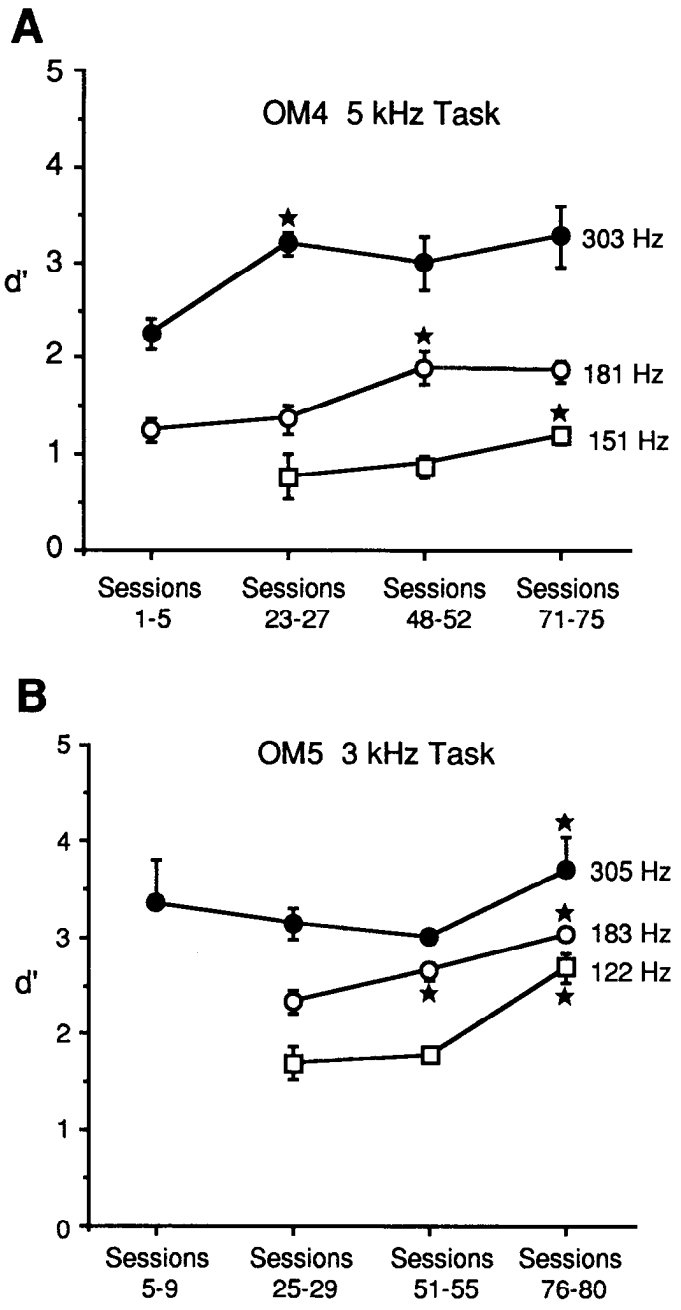

Figure 5. Measures of *d'* for three frequencies as a function of training. The points for a single frequency are connected by a *solid line.* Error bars indicate SE; *stars* indicate statistically significant differences from the preceding measure.

that frequency. This is shown by the performance at 5 kHz in a monkey trained at the 3 kHz task (OM5; open circles, Fig. 1*B*), and by the psychometric functions derived at 3 kHz for a monkey trained at the 5 kHz task (OM4; Fig. 7). In every example, even though there was a significant improvement between these sessions for the trained frequencies, there was little difference in the performance at frequencies that were not trained.

Essentially all training was conducted with the S2 frequencies above the S1 frequency ($+\Delta F$). A somewhat different effect was observed by occasionally testing the performance with decreased S2 frequencies ($-\Delta F$s). On three sessions, OM4 was presented with S2 stimuli in which the second tone of the pair was lower

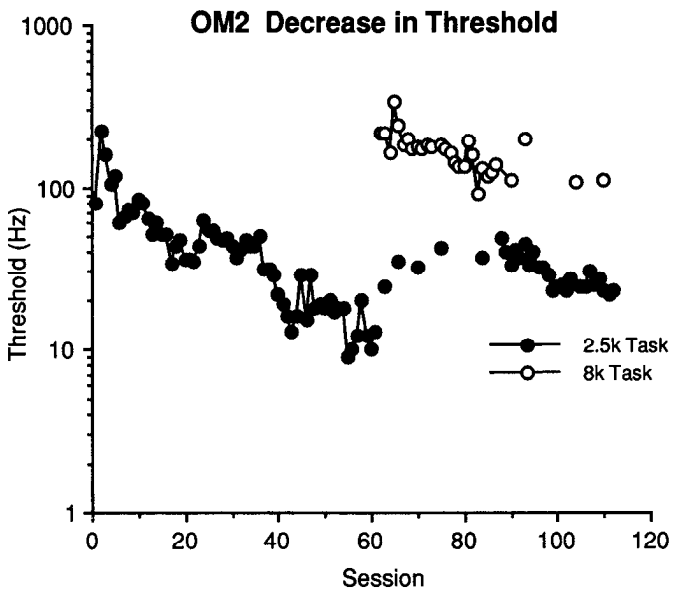

Figure 6. Improvement in frequency discrimination threshold at two different S1 frequencies for monkey OM2. OM2 was initially trained at the 2.5 kHz task (*solid circles*), then changed to the 8 kHz task (*open circles*), and finally returned to the 2.5 kHz task. The 2.5 kHz task was tested intermittently during the consecutive training sessions at the 8 kHz task and vice versa.

in frequency than the first. The psychometric functions from these three sessions are shown in Figure 8 (left), along with three functions using an increased frequency S2 stimulus ($+\Delta F$, right) taken at a similar period of training in the same monkey. The

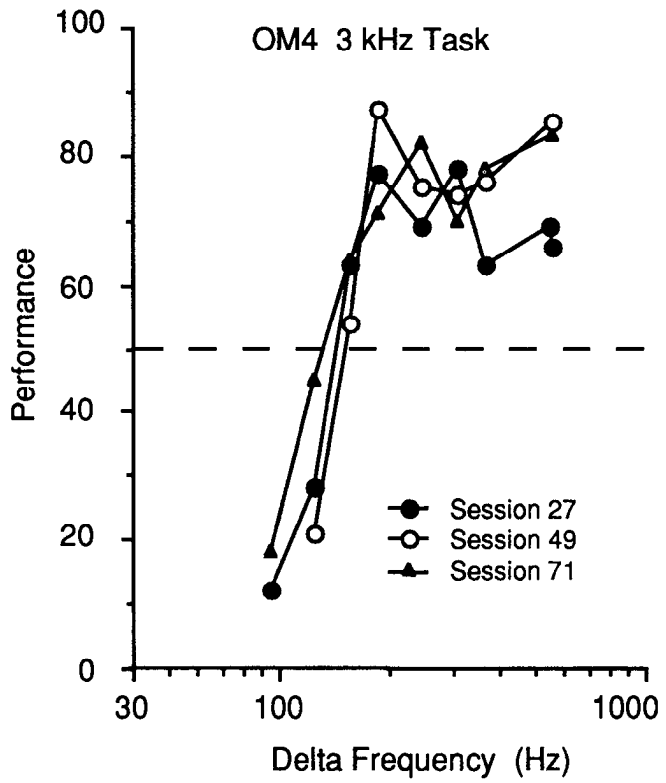

Figure 7. Psychometric functions at three 3 kHz task testing sessions for the monkey trained on the 5 kHz task (OM4). The *broken line* represents performance of 50% (threshold).

Note the increase in performance for the $+\Delta F$ task and the decrease of performance for the $-\Delta F$ task with training.

functions for the $+\Delta F$ values show the improvement in performance as seen in other monkeys. The functions for $-\Delta F$ values, however, show a worsening of performance and an increase in threshold as a function of session. The worst performance at the $-\Delta F$ task was seen on session 70, in which there were 10 intervening sessions using the increasing delta frequencies. This greatest decrease in performance coincides with an increase in the performance for the $+\Delta F$ stimuli. The same test on the 3 kHz task was done in monkey OM5 near the end of the training period, and the threshold for the $-\Delta F$ task ($\Delta F/F = 0.035$) was greater than that observed for the $+\Delta F$ task ($\Delta F/F = 0.028$).

Effect of stimulus intensity. The effects of transference for other frequencies raise the question of how the performance would be affected for other intensities since the training occurred within a limited intensity range of only 10–12 dB. To address this question, psychometric functions were derived at different intensities in monkeys OM4 and OM5 near the end of the training period. There was a slight decrease in frequency discrimination thresholds with increases in intensity (Fig. 9), but these two parameters were not correlated ($p > 0.15$ in both cases).

Electrophysiology

Functional organization of AI. Basic aspects of the functional organization of AI were determined for both the left and right hemispheres in behaviorally trained monkey OM1 and in one hemisphere of monkeys OM3 and OM4. Sufficient electrophysiological data were not obtained from trained monkeys OM2 and OM5 and will not be discussed further. AI was also defined in the two passively stimulated control monkeys CM1 and CM2, and in three behaviorally naive owl monkeys (N1, N2, and N3). Neural responses in laminae III and IV of AI were marked by short-latency (approximately 10–12 msec) responses to a relatively narrow band of frequencies. In general, the low

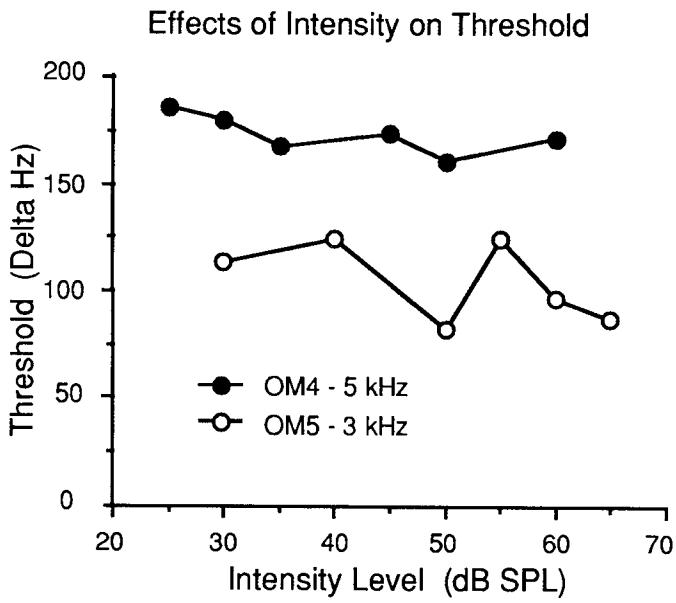

Figure 9. Threshold measured at the trained frequencies as a function of stimulus level for two monkeys, OM4 (*solid circles*) and OM5 (*open circles*). All data were taken from single sessions. The intensity represents the mean intensity measured in the sound field occupied by the monkey's head (see Materials and Methods). Stimulus level varied independently for each tone pip over a range of approximately 15–20% of the mean value plotted.

frequencies were represented on the crown of the gyrus and the higher frequencies were represented down the lateral bank of the sulcus. Neural responses were clustered into "isofrequency bands" where all neurons had similar CFs. These bands were usually oriented oblique to the sulcus but could also be roughly parallel to it. Within the depths of the sulcus, the neural responses would either become very broadly tuned with a higher threshold and longer latency, or become unresponsive to acoustic stimulation. These regions corresponded with the cytoarchitectonic borders of AI as seen histologically, and were characteristic of other auditory cortical fields in this primate species (see Imig et al., 1977; Merzenich et al., 1991).

A central finding of these studies is that the number of recording locations and the cortical area of representation for the frequencies used in the behavioral task were both increased when compared to those frequencies not used in the training. The reconstructed frequency representations from four owl monkeys are shown in Figure 10. Recording locations at which the CF was within the range of frequencies presented in the behavioral tasks are indicated by frequency-specific shading. The total cortical area representing these frequency ranges varied from animal to animal. Some but not all of the differences appeared to be related to the training task. A given frequency was usually represented in a relatively restricted region, but not necessarily continuously. For example, the representation of the frequencies used in the 2.5 kHz task occupied several patches in the trained monkey OM3. By contrast, only a few locations represented these specific frequencies in monkeys not trained at that frequency. Similarly, the greatest representation of the frequencies used in the 5 kHz task were seen in OM4, even though there was only a limited improvement in performance and a relatively small cortical area of representation (Fig. 10*D*). This effect was not seen in the passively stimulated monkey CM2, which received the same acoustic stimulation as OM4, where only a single cortical location represented the frequencies used in the 5 kHz task at CF (Fig. 10*C*). No more than two locations with a CF of 5 kHz were encountered in any of the other monkeys.

The tuning curve data are summarized for all monkeys by plotting the number of cortical locations having a CF within a 500 Hz range (Fig. 11). In Figure 11, the bin size was adjusted to include all the frequencies used in the behavioral tasks (indicated by arrows). In normal owl monkeys, even though all frequencies are represented, there is a consistent underrepresentation of frequencies between 3 and 8 kHz (Fig. 11*A*) and most monkeys showed a relatively large number of recording locations with CFs above 15 kHz. These monkeys also had a large number of locations with a CF near 2 kHz, but those CFs were not in the range used in the 2.5 kHz behavioral task. Each individual monkey showed idiosyncratic increases of particular frequencies, for example, approximately 10 kHz for monkey N2, or approximately 2 kHz for monkey N3.

By contrast, the numbers of locations with CFs in the range of frequencies used in the behavioral task were greatest in monkeys trained at that frequency range. In the trained monkey, the number of locations near 8 kHz was approximately 3–10 times greater in both hemispheres compared to normal and control monkeys (Fig. 11*B*). Monkey CM1, which received the same acoustic stimuli as OM1 but was not required to attend to these stimuli, had an essentially normal representation of these frequencies. The frequency range used in the 2.5 kHz task was represented by more locations in the monkey trained at that task than in any other monkey. The same was true for the frequency range used in the 5 kHz task (Fig. 11*C*).

The larger number of cortical locations that represented the trained frequencies could not be explained by an increase in the sampling density over that region, as the representation of these frequencies and surrounding areas was defined at equivalent density in all monkeys. This increase was better explained by an increase in the cortical area of representation of those frequencies. Figure 12 shows the cortical areas associated with each of the three different frequency ranges for all monkeys. In every case, the area of representation for the behaviorally relevant frequencies for a trained monkey (solid bars) was significantly greater than the cortical areas for those frequencies in all other monkeys, including those that were passively stimulated (hatched bars).

Response properties at individual locations. The tuning properties of the neurons at each recording location were investigated by recording FRAs at all AI recording locations of monkeys OM1, OM3, CM1, and in each of the three normal monkeys. Measures of Q10dB were made at each location; examples are plotted in Figure 13. In every monkey, the values for Q10dB tended to increase with increasing frequency, consistent with reports from other species (see Pelleg-Toiba and Wollberg, 1989; Schreiner and Mendelson, 1990). There was a considerable range of Q10dB values for any given frequency in all monkeys. The Q10dB measures for neurons in trained monkeys were greater (tuning bandwidths were narrower) for the behaviorally trained frequencies when compared to normal or passive stimulation control monkeys. The mean Q10dB and Q40dB for all monkeys over the frequency range used in the 2.5 or 8 kHz tasks are shown in Figure 14*A*. The left and right hemispheres of OM1 are considered independently, and the data from the three normal monkeys are pooled. Measures of Q10dB were statistically significantly greater over the behaviorally trained frequencies in trained monkeys when compared to the three normal controls. The Q10dB of the passive control animals was also elevated over that of normal control monkeys. Statistically significant increases in Q40dB were noted only in the right hemisphere of OM1 for the 8 kHz frequencies.

In addition to the increase in Q10dB, there was also an increase in the minimum latency of the response for the behaviorally trained hemispheres in each of the three cases (Fig. 14*B*). Response latencies in the passive stimulation monkey were not significantly different from those in control monkeys. The variance of the latencies was very low in all monkeys, as indicated by the small SE bars. The distribution of the variance in the latency measure was not statistically significantly different between the normal monkeys and any others ($p > 0.1$).

Correlation of behavioral performance with neural responses. The main objective of these studies was to determine (1) if the functional organization of the primary auditory cortex was altered consequent to training the animal in an acoustic discrimination task, and (2) if the resulting cortical representations were correlated with the behavioral performance. The three measures showing significant changes in trained monkeys described above, the increased cortical area, increased Q10dB (narrower bandwidths near threshold), and increased latency, were subjected to regression analysis. For these analyses, behavioral performance was taken as the threshold measured at the end of the training sessions for the trained monkeys, and paired with the electrophysiological measures derived from those same monkeys. To estimate the behavioral performance of "untrained"

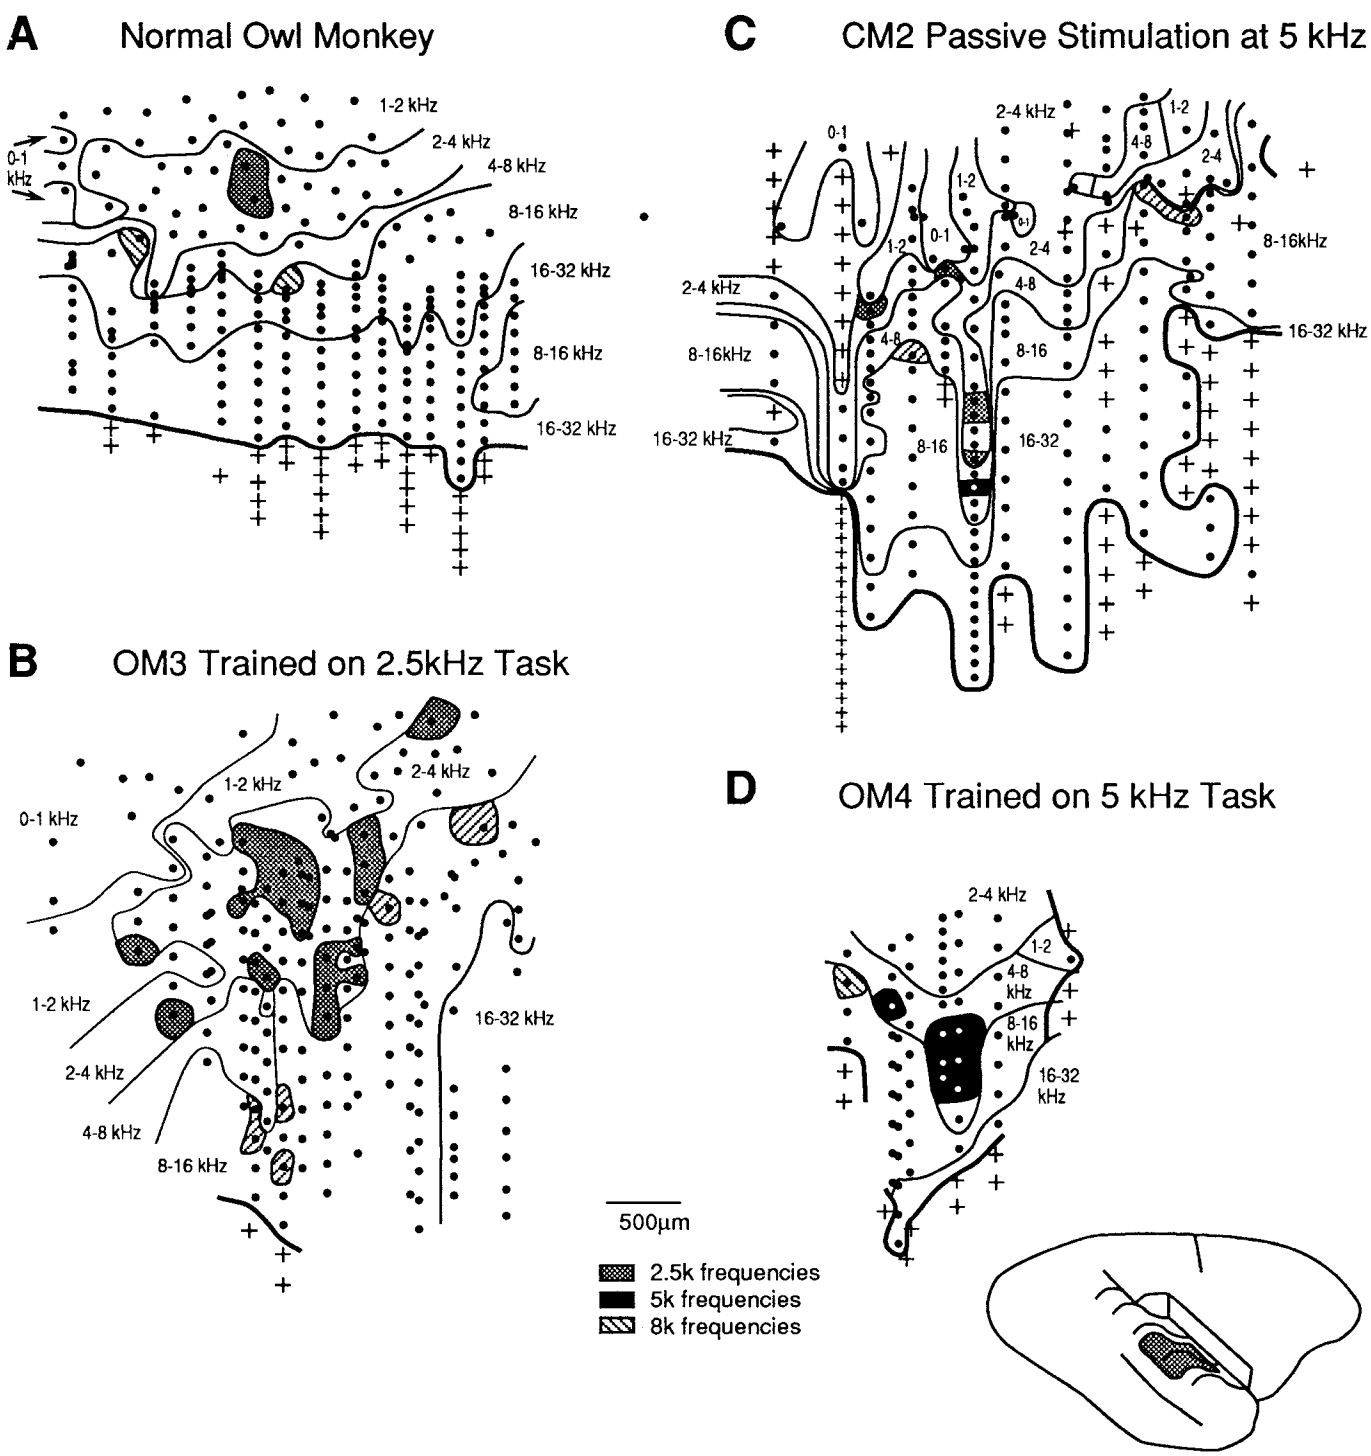

Figure 10. Cortical representations of CF in AI of four adult owl monkeys. *Thin lines* define boundaries of cortical locations with CFs within one octave. *Stippled regions* encircle cortical locations where neurons were recorded with CFs in the frequency range used in the 2.5 kHz task, *solid regions* represent frequencies used in the 5 kHz task, and *hatched regions* represent the frequency range used in the 8 kHz task. The cortical areas representing a given frequency range were approximated by connecting the 50% distance values to the neighboring recording sites with CFs outside the given frequency range. *Pluses* denote recording sites with neuronal responses not consistent with properties of AI neurons. *A* is from a representative normal owl monkey (N2), *B* is from a monkey trained at 2.5 kHz (OM3), *C* shows the monkey passively stimulated with the frequencies used in the 5 kHz task (CM2), and *D* shows the representation of the monkey trained at the 5 kHz task (OM4).

monkeys, the mean threshold of training sessions 5–10 for monkeys OM3 and OM1 were used for the 2.5 kHz and 8 kHz tasks, respectively. These sessions were used because they showed less variability than the initial five sessions (1–5) and probably better reflect the monkey's true initial discrimination abilities (see Discussion). For the "untrained" behavioral performance of the 3 kHz and 5 kHz tasks, the mean thresholds for the two and six sessions at these tasks for monkeys OM4 and OM5 were used, respectively. These "untrained" behavioral measures were considered with the electrophysiological results pooled from the untrained monkeys. The values of Q10dB, Q40dB, and minimum latency showed no significant correlation with these be-

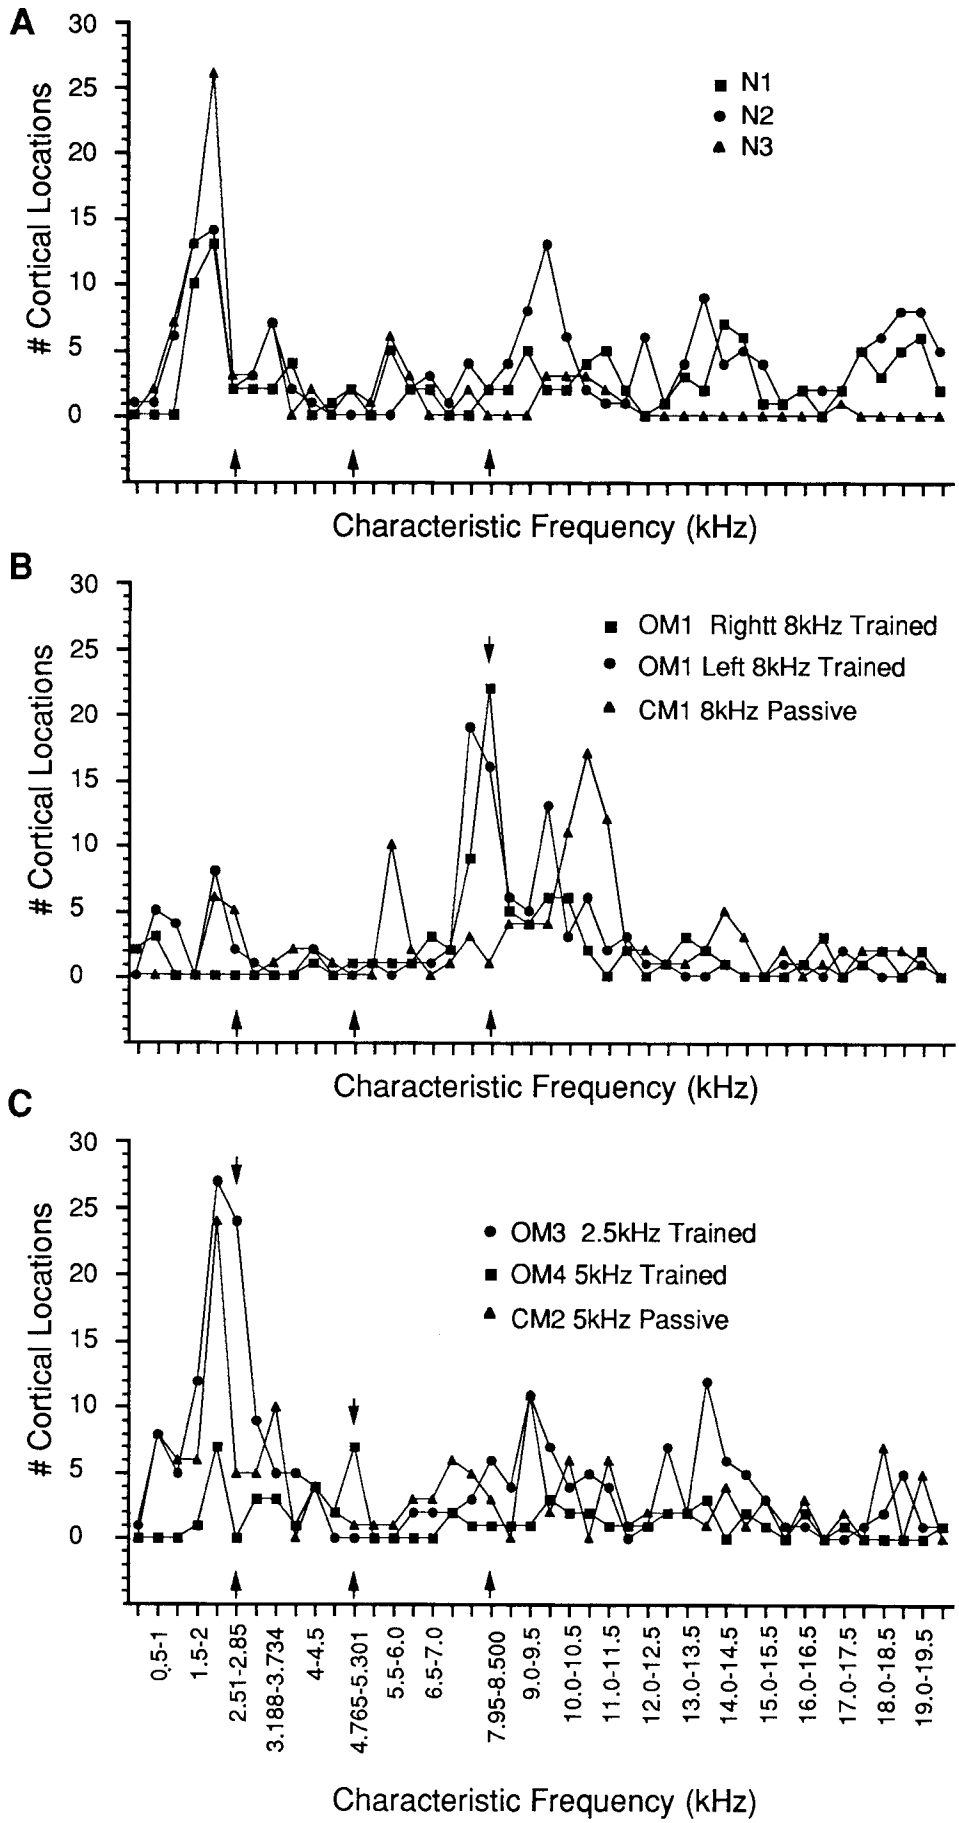

Figure 11. The number of cortical locations plotted by CF in 500 Hz bins. Bin size was adjusted to incorporate all frequencies used in the behavioral task into a single bin (indicated by *arrows*). The three normal monkeys are shown in *A*, the two hemispheres from monkey OM1 and the passive-stimulation control monkey CM1 are shown in *B*, and the monkeys trained at the 5 kHz and 2.5 kHz task (OM4 and OM3) and the passively stimulated monkey CM2 are shown in *C*.

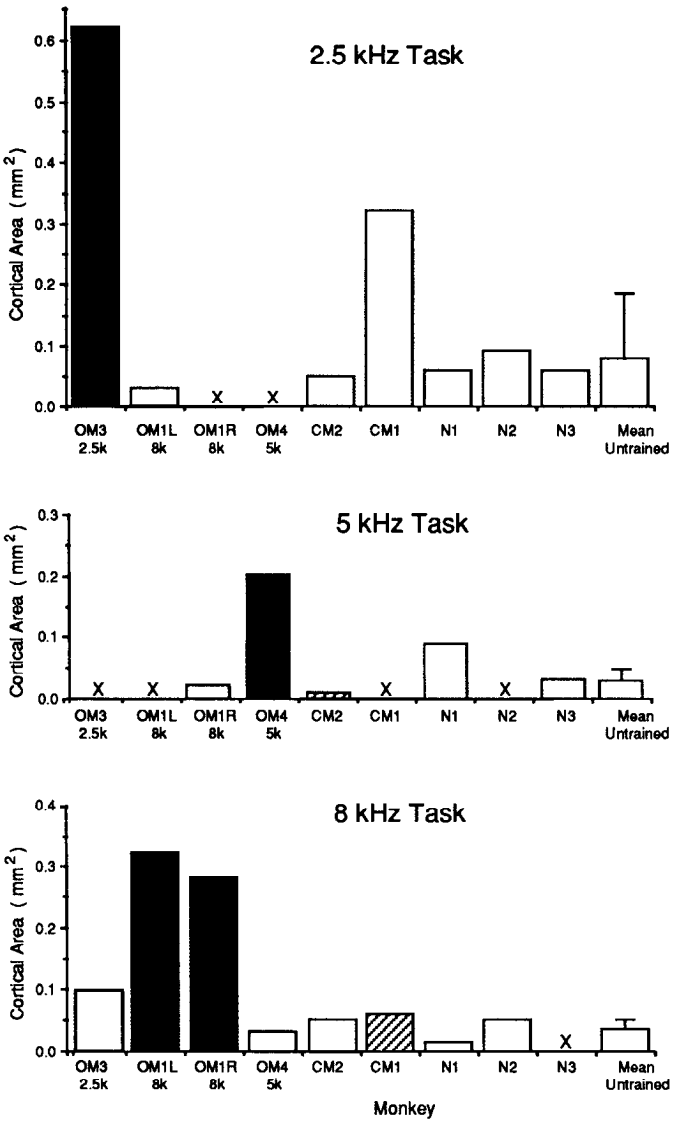

Figure 12. Cortical area of representation of the frequency ranges used in the behavioral study. *Solid bars* indicate the area of representation of the trained frequency for that particular monkey; *hatched bars* represent areas of the frequencies presented to the passive-stimulation control monkeys. *Crosses* represent hemispheres where no cortical locations were recorded with a CF within that frequency range. The column "*Mean Untrained*" represents the mean and SD for all hemispheres excluding the trained hemispheres.

havioral measures (p = 0.44, 0.21, and 0.91, respectively). By contrast, the correlation analysis of behavioral threshold with cortical area revealed that these two parameters were significantly correlated (Fig. 15; r = 0.88; $p < 0.01$; df = 6).

Discussion

Improvements in behavioral performance in an auditory frequency discrimination task were recorded in five adult owl monkeys. There was a roughly sequential improvement in performance at individual S2 frequencies, which was expressed in a shift of the psychometric function and an increase in the slope of the function near threshold. The improvement in performance was much less for untrained frequency ranges, and the performance was independent of stimulus level between 25 and 65 dB SPL. Electrophysiological mapping experiments revealed

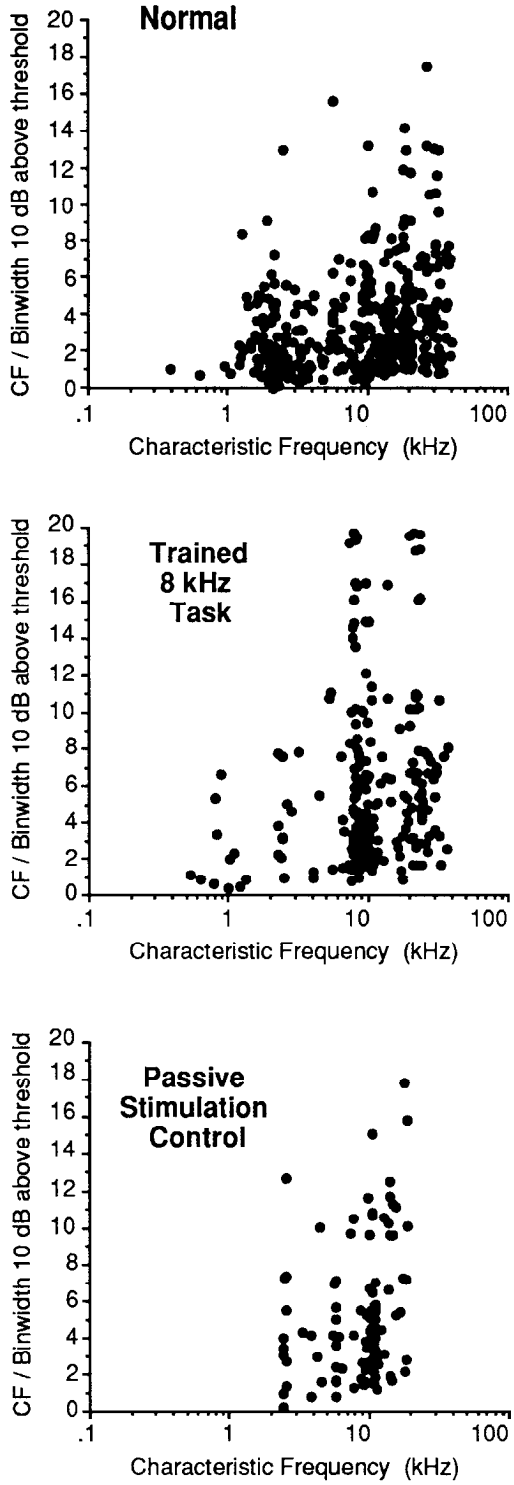

Figure 13. Values of Q10dB as a function of CF. Normal owl monkeys N1, N2, and N3 are pooled and shown in the *top panel*, both hemispheres of trained monkey OM1 in the *middle panel*, and the passive stimulation control monkey CM1 in the *bottom panel*. Each point represents the CF and Q10dB at a single recording location.

a larger cortical area of representation of the behaviorally trained frequencies, sharper tuning as measured by Q10dB but not Q40dB, and longer response latencies over the frequency range used in the behavioral task. The cortical area of CF representation was the only measured parameter that was significantly

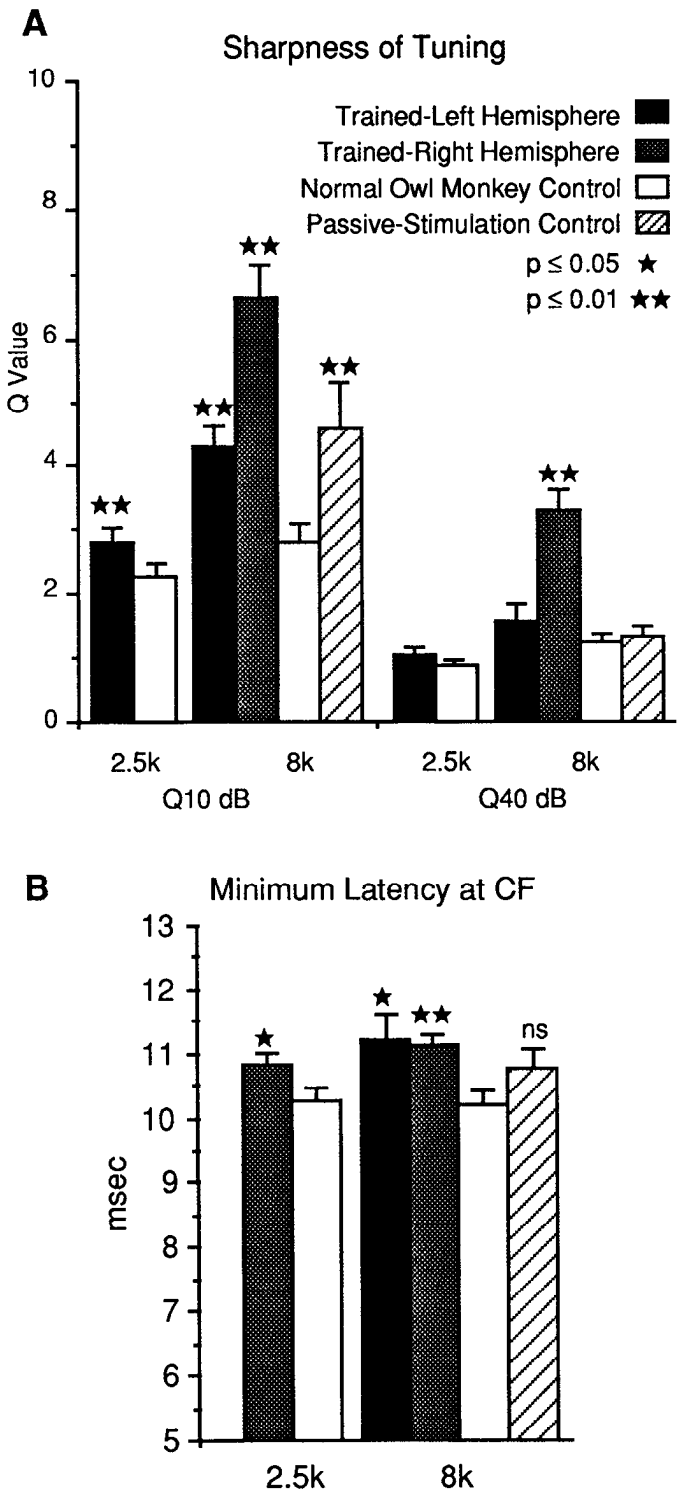

Figure 14. Comparison of sharpness of tuning (*A*) and minimum latency (*B*) for different training conditions. Data from each experimental and passive-stimulation hemisphere are shown as a single bar, with the data from the three normal monkeys combined (*open bars*). *Stars* indicate statistically significant differences from the normal hemispheres. Data are pooled for all recording locations with CFs between 1.9–3.1 kHz (2.5 kHz task) and 6.6–9.9 kHz (8 kHz task). *A*, Mean and SE of Q10dB (*left*) and Q40dB (*right*) for all studied monkeys. *B*, Minimum latency of the response for the 2.5 kHz (*left*) and 8 kHz tasks (*right*).

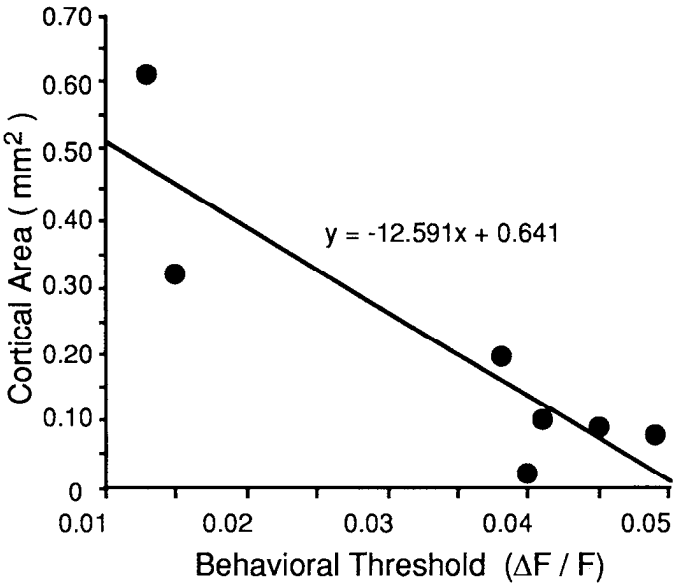

Figure 15. Correlation analysis of the cortical area of representation of the behaviorally trained frequencies at CF with the behavioral threshold. The equation describes the line with the root mean square best fit to the data ($r = 0.882$, $P < 0.01$, df = 6).

correlated with behavioral frequency discrimination performance.

Behavioral thresholds measured in this study were similar to those described for other nonhuman primates for the 2.5 kHz and 8 kHz tasks (Sinnott et al., 1985, 1987; Prosen et al., 1990), but were higher than those recorded in humans (Wier et al., 1977; Sinnott et al., 1985, 1987). The frequency discrimination thresholds measured for the 3 kHz and 5 kHz tasks were greater than those measured for this frequency range in Old-World monkeys. That may be the result of an attenuation of these middle frequencies in this particular species, for example, by physical constraints imposed by the outer or middle ear. These higher-frequency discrimination thresholds are consistent with the relatively high behaviorally measured detection thresholds in the frequency range of 3–6 kHz in this species (Beecher, 1974), the relatively small cortical representation of this frequency range in AI of normal owl monkeys (Imig et al., 1977; present results), and the higher response thresholds of AI neurons over this frequency range in this and other New-World monkey species (Aitkin et al., 1986; Merzenich et al., 1991).

The electrophysiological experiment revealed a tonotopic organization of owl monkey AI similar to that previously shown in this species (Imig et al., 1977) as well as other primates (Merzenich and Brugge, 1972; Aitken et al., 1986). The responses of neuronal clusters to these tonal stimuli were commonly very brisk, with an initial short-latency burst of activity. In spite of the globally smooth tonotopic organization in AI, the representation of very small frequency ranges was often seen to be patchy for both the experimental and control hemispheres. Part of the explanation is that we were basing the area measurements on the CF at threshold, and considered only a very small frequency range. It is likely that this patchy representation would be more continuous if considered from the view of either a higher-intensity stimulus or over a larger frequency range. However, the presence of patches of representation of some frequencies may accurately reflect the tonotopic organization at

this level of detail, as a similarly discontinuous representation of restricted frequency ranges can be seen in the detailed maps of AI described in the marmoset (Aitkin et al., 1986).

Neural mechanisms of frequency discrimination. The finding that the cortical area of CF representation was correlated with the behavioral performance does not restrict the site of frequency discrimination to that location. Most nuclei throughout the central auditory pathways could contribute to these perceptual distinctions. Studies have indicated that large lesions that include AI do not effect learned frequency discriminations in cats (Butler et al., 1957; Goldberg and Neff, 1961), but deficits have been shown in other behavioral paradigms (Meyer and Woolsey, 1952; Thompson, 1960). These studies suggest that the sequence and timing of stimuli, or perhaps the difficulty of the task, affect the necessary contribution of auditory cortical fields regarding this behavior. The behavioral task used in these experiments cannot be directly compared to those cited above, yet were considered by human observers to be quite difficult and to require vigilant attention in order to perform correctly. An alternative view is that the pairs of tone pips presented sequentially in the present study more closely match auditory pattern discrimination paradigms, which do show deficits following auditory cortical lesions (Diamond and Neff, 1957). A third point to bear in mind is that the limited data available suggest that thalamic areas with frequency-specific responses (ventral medial geniculate nucleus) are less affected by classical conditioning paradigms than the cerebral cortex, although the responses of the more broadly tuned neurons located in the magnocellular division of the medial geniculate are affected by classical conditioning paradigms (see Weinberger et al., 1990, for review). The cortical representations described in this report may be a reflection of tonotopically reorganized subcortical regions, partially reorganized subcortical and cortical areas, or resulting from reorganization only at the cortical level.

Regardless of the fact that we cannot identify the site(s) of reorganization, the differences in the response properties of AI neurons between trained and untrained monkeys do provide some insights into plausible neural mechanisms of frequency discrimination. Frequency discrimination abilities could potentially be based on either the rate of neuronal discharge, the temporal information encoded within the discharge, and/or the spatial location/distribution of the neurons responding to the different frequencies. Our finding of an increased spatial representation of behaviorally relevant frequencies suggests that the spatial distribution of central neurons at least contributes to this behavior. One simple hypothesis is that the separation in the spatial locations of appropriately tuned neurons could provide the necessary information to form the basis of the discrimination. Increases in the representation of a frequency range would increase the spatial resolution of those frequencies. The fact that the bandwidth of the tuned response was not significantly different at 40 dB above threshold suggests that this larger representation was maintained at higher intensities, for example, those used in the behavioral paradigm. However, the cortical area measure at CF described here is almost certainly an oversimplification. By combining the several islands of cortical representation into a single measure, we may have diluted the contributing portion. Studies in the cat have shown that several different parameters of both tuning and timing of the neural response are topographically organized along the isofrequency axis (Mendelson et al., 1988; Schreiner et al., 1988; Schreiner and Mendelson, 1990; Imig et al., 1991; Sutter and Schreiner, 1991), and preliminary data suggest that this is also the case in the owl monkey (Merzenich et al., 1991). It is plausible that only a subset of the total area of representation is contributing to the processing of frequency distinctions, while other parts of the representation are processing other stimulus parameters. Finally, the neural responses were not tested with respect to the their temporal representation of the stimuli. Studies in somatosensory cortex have shown that the occurrences of neural discharges are temporally more coherent in monkeys trained at a tactile frequency discrimination task when compared to unstimulated and passively stimulated monkeys (Recanzone et al., 1992d). The temporal coding of the stimuli could provide additional information regarding frequency.

The finding that Q10dB did increase significantly was unexpected, as the behavioral stimuli were not presented at these low intensities. The disparity between Q10dB and Q40dB suggests that these two parameters are not equivalent, consistent with observations in cat (Schreiner and Mendelson, 1990; Sutter and Schreiner, 1991). Q10dB measures have been reported to covary with latency, and both were observed to increase in the trained monkeys. The longer latencies in the trained monkeys may have resulted from increased neural processing at subcortical levels, or perhaps from a suppression of normally shorter-latency inputs that are involved in processing other aspects of the acoustic signal. These two parameters were not correlated with the behavioral performance, as the higher Q10dB (narrower bandwidths) and latency measures were not matched with the lowest thresholds.

Finally, both hemispheres were investigated in only one monkey. The hemisphere studied in each of the other trained monkeys was selected as the hemisphere contralateral to the ear nearest the speaker in the behavioral apparatus. In most cases, the monkey oriented its head either directly toward the speaker, in which case the ears were at an equivalent distance, or toward the food hopper, which would slightly favor one ear over the other. Both hemispheres of OM1 had similar areas of representations; however, there were significant differences between the right and left hemispheres with respect to both Q10dB and Q40dB. It is unclear at present how these binaural stimuli are processed by the two hemispheres.

Comparisons with earlier studies. The caveats discussed above do not detract from the findings that there is a significant improvement in behavioral performance at the frequency discrimination task with training that was significantly correlated with the spatial representation of the trained frequencies in primary auditory cortex. Improvements in performance at a perceptual or motor skill have been well documented for a variety of tasks (see Volkmann, 1858; James, 1890; Gibson, 1953; Fitts, 1964), including relatively simple sensory discrimination tasks in adult primates (Sinnott et al., 1985; Prosen et al., 1990; Recanzone et al., 1992a), and have been shown to continue for up to several years of continuous practice. The initial, rapid component of the improvement probably represents a "conceptual" learning of the task and development of the most appropriate strategies (see deJong, 1957; Crossman, 1959; Seibel, 1963; Recanzone et al., 1992a). This is supported by the large variability in the performance between these early sessions, and by the fact that it was not seen when the task was changed to different frequencies in well-trained monkeys (e.g., 2.5 kHz to 8 kHz in OM2).

The second stage of learning was characterized by an improvement in performance at each S2 frequency in a roughly sequential fashion, and an increase in the slope of the psycho-

metric function at threshold. This improvement has been hypothesized to result from an enhancement of the central representation of the appropriate stimulus parameters (Recanzone et al., 1992a,d). The psychophysical results derived in these monkeys are in agreement with this hypothesis. For example, there was little transference of the improvement in performance when untrained frequency ranges were tested in widely separated sessions, consistent with studies on absolute auditory detection thresholds (Zwislocki et al., 1958) or tactile frequency discrimination thresholds (Recanzone et al., 1992a). Improvements were only recorded when training was continuous for several days. The representations of these untrained frequencies were comparable to those of normal monkeys. An interesting observation was the apparent decrease in performance for decreasing S2 frequencies ($-\Delta F$ values) with training at increasing S2 frequencies ($+\Delta F$ values). The thresholds for $-\Delta F$ values have been reported to be slightly lower in humans but vary depending on the species for Old-World monkeys (Sinnott et al., 1987). In those experiments, the behavioral performances were reported following training at both increasing and decreasing ΔF tasks. In OM4, where several measures of $-\Delta F$ threshold were made, there were no cortical locations observed where the CF was centered in the range of these decreasing S2 frequencies. Finally, our psychophysical results suggest that there is little, if any, effect of stimulus level on discrimination performance. There was a slight decrease in threshold with increasing stimulus level, but this difference was not statistically significant. Increasing intensity can increase frequency discrimination ability in humans, but decreases performance in macaque monkeys (Sinnott et al., 1987). Our results suggest either that frequency discrimination performance is normally independent of stimulus level in this species, or that the performance at the trained stimulus level improved to match that for lower stimulus levels. The effects of stimulus amplitude on frequency discrimination in a naive animal of this species would provide further information on this issue.

The electrophysiological results are consistent with a variety of preparations in the somatosensory system (for reviews, see Merzenich et al., 1988, 1990; Kaas, 1991) and with the hypothesis that the functional organization of the cortex changes in parallel with perceptual changes (see Merzenich et al., 1988, 1990; Recanzone et al., 1991b,d; Recanzone and Merzenich, 1992). The finding that the large cortical representation of the behaviorally trained receptor surface was only seen in monkeys trained to discriminate those frequencies, and not in monkeys trained at an unrelated task, is consistent with results from the somatosensory system (Jenkins et al., 1990; Recanzone et al., 1992b–d). This representational plasticity occurred even though the monkeys in this study were acoustically stimulated for approximately 15–20 min during the 2 hr session each day, and were allowed to hear other auditory stimuli, some of which were presumably behaviorally significant, for the remaining 22 hr each day. Thus, it is not necessary to present the behaviorally important stimuli to the exclusion of all other stimuli for these effects to occur, and consistent with reports on the effects of classical conditioning on responses of auditory cortical neurons, behavioral relevance of the stimulus is necessary.

The demonstration that there is a larger CF representation in trained monkeys is not altogether unexpected given the frequency-specific changes in neural responses of other auditory cortical areas following classical conditioning paradigms in the cat (Diamond and Weinberger, 1986) and guinea pig (Bakin and Weinberger, 1990) and changes in the tonotopic representation of AI after restricted cortical lesions in the adult guinea pig and cat (Robertson and Irvine, 1989; Irvine et al., 1991). In contrast to the conditioning studies, there was no obvious change in the overall responsiveness of neurons representing the frequencies used in behavioral training, and there was no significant change in the tuning of these neurons at intensities well above threshold. Similarly, several months after restricted lesions in the cochlea, the overall activity of neurons in the expanded zone of CF representation in AI is similar to neurons in the adjacent, unaffected region. These differences may reflect differences in the comparison between short-term effects as in the conditioning studies and the long-term effects as in this and the lesion studies, in the anesthetic state of the animal, or in the differences between the conditioning and discrimination behavioral paradigms.

Several models advanced to account for cortical plasticity have proposed that synaptic efficacies are altered consequent to the temporal correlation of pre- and postsynaptic activity by a Hebbian mechanism (e.g., see Edelman, 1987; Merzenich et al., 1988, 1990; von der Malsburg and Singer, 1988; Palm, 1990; Singer, 1990; Weinberger et al., 1990). These mechanisms, although presented with respect to the cerebral cortex, could be equally effective for representational changes in subcortical areas. Computer models using these types of synaptic efficacy changes result in changes in topography similar to those observed in the somatosensory (Pearson et al., 1987; Grajski and Merzenich, 1990) and visual cortices (Miller et al., 1989). The present results are consistent with models of this class, as the increased area of representation and the increased sharpness of tuning could result from the strengthening of the synapses representing the behaviorally trained frequencies, and a weakening of synapses representing other, neighboring frequencies. The unaffected representations in the passive stimulation monkeys suggest that attention to the stimulus enhances the response, perhaps via neuromodulators such as ACh or norepinephrine (see Singer, 1990; Weinberger et al., 1990).

The inverse relationship between receptive field size and the cortical area of representation described in the visual and somatosensory systems (Hubel and Wiesel, 1974; Sur et al., 1980) is thought to arise by competitive interactions of excitatory and inhibitory inputs between cortical neurons comprising a horizontally oriented network (see Edelman, 1987; Merzenich et al., 1990). These local interactions between cortical neurons would also restrict the improvement to the behaviorally trained and immediately surrounding frequencies, and thus only limited effects on either the cortical representation or behavioral performance for other frequencies are expected. The decreasing performance at $-\Delta F$ frequencies observed in this study suggests that these horizontal influences degrade the representation of unused neighboring frequencies, perhaps by "borrowing" territory from the representation of those frequencies. The local interactions would also be expected to sharpen the temporal cohesiveness of the responses over a wider area, as has been demonstrated in the somatosensory cortex (Recanzone et al., 1992d), which would result in a stronger representation of the stimulus in both space and time that could then be transmitted to other areas for further processing.

Technical considerations. Several technical considerations must be remembered when attempting to correlate data derived by presenting single tone bursts in a closed sound system in an anesthetized monkey with behavioral measures performed using sequential tone bursts in the free field. The barbiturate anes-

thesia may have masked differential neuronal responses to behaviorally relevant stimuli. The effects of barbiturate anesthesia on tuning properties of cells in AI of the monkey are not well described; however, comparison of our data with that of others derived in awake animals (i.e., Funkenstein and Winter, 1973; Pelleg-Toiba and Wollberg, 1989) suggests little effect on measures of CF or temporal response properties of cortical neurons. In this study, all of the comparisons of the neural responses were made between monkeys anesthetized in a similar manner; thus, all anesthetic effects are constant and do not differentially affect one set of monkeys.

A second consideration is that the stimuli used in generating the cortical maps were shorter in duration (50 msec vs. 150 msec) and were presented through a closed sound system. The acoustic environment in the free field and the resonance properties of the external ear may have distorted the stimuli in the behavioral condition. The definition of response properties of AI neurons using a closed sound system has the advantage of better control of the stimulus intensity within and between individual experiments. Direct comparisons can also be made between these results and those of others. If the electrophysiological experiments were performed in the free field, idiosyncratic distortions of the stimulus could occur between individual monkeys due to variations in head size and location and pinna morphology. To match the acoustic environment of the behavioral apparatus in the electrophysiology experiment, it would have been necessary to perform both in the same apparatus, which was not possible. Finally, the technique we have used is appropriate to achieve the primary goal of the study, namely, to define alterations in the tonotopic organization of AI consequent to the behavioral training.

A third potential problem is in correlating the pooled data from normal monkeys with the behavioral results from other monkeys either early in training or when tested on untrained frequencies. This method increased the number of data points such that reasonable correlation analysis between physiological and behavioral data could be performed, but is based on the assumption that the physiological and behavioral measures are representative for all monkeys. The estimates of "untrained" behavioral performance are probably reasonable because the thresholds for sessions 5–10 in monkey OM1 were within 15% of the initial five sessions for OM2 at the 8 kHz task, as were the measures for sessions 5–10 for monkeys OM2 and OM3 in the 2.5 kHz task. These differences were not significantly different, and all of our data for both auditory and tactile frequency discrimination measures using this paradigm show low interindividual variability (see Recanzone et al., 1991, 1992a). There was also some variability in the cortical representations between normal monkeys, as has been seen previously in AI (Merzenich and Brugge, 1973; Imig et al., 1977; Aitken et al., 1986; see also Merzenich et al., 1975), consistent with interanimal variability described in primary somatosensory cortex (Merzenich et al., 1987). This variability was most evident in the large representation of frequencies in the range of 10 kHz in monkey N2 and for frequencies near 11 kHz in monkey CM1. This interanimal variability of frequency representations was reduced when considered from the point of view of the expanded representations in the trained monkeys, where cortical representations were invariably several times greater than the mean representations from untrained hemispheres. These idiosyncrasies of primate AI organization prompted us to utilize the strategy of using different comparison frequencies for each of the limited number of owl monkeys trained in the behavioral task. Obviously, if one had trained monkey N2 on a 10 kHz task, they may have been misled by the preexisting large representation of those frequencies. By the same logic, the probability of matching the frequency in the behavioral paradigm with the idiosyncratically overrepresented frequency in each of the studied individual monkeys is remote.

One potential inadequacy of the data is that frequency response areas, and hence the measures of Q10dB and Q40dB, were based on the single presentation of each of the 675 stimuli. Spontaneous activity occurring in the 50 msec time window of data collection could artificially broaden the response area, and only stimuli that evoke a response on several repeated trials might be consistently considered within the response area. However, this method has been shown to be a reliable measure of multiple-unit responses. The objective criteria used to define Q10dB and Q40dB take into account the rate of spontaneous activity as well as the consistency of the response latency, and have been argued to accurately reflect the tuning and timing properties of the neurons under study (see Schreiner and Mendelson, 1990; Sutter and Schreiner, 1991). The minimum latency estimate was based on all 15 levels at three frequencies, and therefore represents 45 separate measurements.

Concluding remarks. The demonstration that the extent of the cortical area of representation of a specific frequency range is correlated with the behaviorally measured discrimination performance represents a first approximation for determining the neural correlate of this perceptual judgement. The results of these experiments are consistent with hypotheses that auditory cortical representations are modifiable and that this plasticity reflects the acquisition of skills and behaviors throughout life. A key prediction from these hypotheses is that the changes in cortical representation should occur in parallel with the behavioral gains, and repeated measures of these representations should correlate with the repeated measures of behavioral performance. A second prediction is that inactivation of restricted areas of the central representation of these stimuli should result in restricted behavioral deficits. Finally, the effects of interrupting the normal release of putative neuromodulators during the period of acquisition of this behavioral improvement could begin to reveal the pharmacology of this representational plasticity as has been done in other systems (i.e, Kasamatsu and Pettigrew, 1979; Bear and Singer, 1986). Such studies would provide key evidence in extending these hypotheses and models of cortical function.

Dopamine (DA) signals in the striatum are critical for a variety of vital processes, including motivation, motor learning, and reinforcement learning. Striatal DA signals can be evoked by direct activation of inputs from midbrain DA neurons (DANs) as well as cortical and thalamic inputs to the striatum. In this study, we show that *in vivo* optogenetic stimulation of prelimbic (PrL) and infralimbic (IL) cortical afferents to the striatum triggers an increase in extracellular DA concentration, which coincides with elevation of striatal acetylcholine (ACh) levels. This increase is blocked by a nicotinic ACh receptor (nAChR) antagonist. Using single or dual optogenetic stimulation in brain slices from male and female mice, we compared the properties of these PrL/IL-evoked DA signals with those evoked by stimulation from midbrain DAN axonal projections. PrL/IL-evoked DA signals are undistinguishable from DAN evoked DA signals in their amplitudes and electrochemical properties. However, PrL/IL-evoked DA signals are spatially restricted and preferentially recorded in the dorsomedial striatum. PrL/IL-evoked DA signals also differ in their pharmacological properties, requiring activation of glutamate and nicotinic ACh receptors. Thus, both *in vivo* and *in vitro* results indicate that cortical evoked DA signals rely on recruitment of cholinergic interneurons, which renders DA signals less able to summate during trains of stimulation and more sensitive to both cholinergic drugs and temperature. In conclusion, cortical and midbrain inputs to the striatum evoke DA signals with unique spatial and pharmacological properties that likely shape their functional roles and behavioral relevance.

Key words: DA release; dorsomedial striatum; fast-scan cyclic voltammetry; optogenetics; PFC

Significance Statement

Dopamine signals in the striatum play a critical role in basal ganglia function, such as reinforcement and motor learning. Different afferents to the striatum can trigger dopamine signals, but their release properties are not well understood. Further, these input-specific dopamine signals have only been studied in separate animals. Here we show that optogenetic stimulation of cortical glutamatergic afferents to the striatum triggers dopamine signals both *in vivo* and *in vitro*. These afferents engage cholinergic interneurons, which drive dopamine release from dopamine neuron axons by activation of nicotinic acetylcholine receptors. We also show that cortically evoked dopamine signals have other unique properties, including spatial restriction and sensitivity to temperature changes than dopamine signals evoked by stimulation of midbrain dopamine neuron axons.

Introduction

The striatum receives dense innervation from midbrain DA neurons (DANs), which are the main source of DA in the striatum. DA plays a critical neuromodulatory role in regulating striatal circuitry and function (Surmeier et al., 2007; Gerfen and Surmeier, 2011; Burke et al., 2017). Disruptions in striatal DA levels are associated with many neurologic and psychiatric disorders, such as Parkinson's disease and substance abuse disorder (Gerfen, 2000; Luscher et al., 2020). DA is released from a fraction of the varicosities distributed along DAN axons, which contain specialized active zone-like sites (Sulzer et al., 2016; Liu et al., 2018; Liu and Kaeser, 2019). The axonal arborizations of DANs ramify extensively within the striatum, and a single dopamine axon can spread over a significant area (~3% in average)

of the striatum (Matsuda et al., 2009). DA released from axonal varicosities generates a rapid increase in local extracellular DA concentration. This extracellular increase leads to the activation of multiple types of DA receptors, which are localized in dendrites, somas, and presynaptic terminals. Ultimately, this impacts the network activity of the striatum and drives behavior output (Tritsch and Sabatini, 2012; Chuhma et al., 2014; Mamaligas et al., 2016; Burke et al., 2017; Shin et al., 2017; Lahiri and Bevan, 2020). This striatal DA signal is known to be triggered by two mechanisms. One mechanism involves action potential firing initiated at midbrain DAN somas, which propagates through dense axonal arborizations to reach active zone-like release sites in the striatum (Matsuda et al., 2009; Liu et al., 2018). In the other mechanism, DAN axons in the striatum are locally activated, independent of the action potential firing at DAN somas. This mode of DA release requires the activation of nAChRs expressed on DAN axons and synchronized activation of cholinergic interneurons (CINs), which is thought to give rise to local release of ACh (Cachope et al., 2012; Threlfell et al., 2012; Wang et al., 2014; Shin et al., 2015, 2017).

This local intrastriatal trigger of DA release has only recently been demonstrated and is gaining attention as it represents a newly discovered means for striatal DA modulation/transmission. However, little is known about the differential/unique biophysical and pharmacological properties of locally evoked versus DAN-evoked DA transmission. Recent *in vitro* studies using optogenetic stimulation and fast-scan cyclic voltammetry (FSCV) show that local DA signals can be triggered in the striatum by stimulation of glutamatergic inputs from thalamus (Threlfell et al., 2012; Kosillo et al., 2016; Johnson et al., 2017; Cover et al., 2019), motor cortex (Kosillo et al., 2016), or PFC (Mateo et al., 2017). These findings agree with previous literature showing *in vivo* DA signals in the striatum evoked by stimulation of PFC (Taber and Fibiger, 1993; Quiroz et al., 2016; Hill et al., 2018), hippocampus (Tritschler et al., 2018), or amygdala (Floresco et al., 1998). Furthermore, *in vivo* intrastriatal administration of glutamate and ACh was also shown to cause increases in extracellular DA concentration in the rat striatum (Giorgieff et al., 1976, 1977; Leviel et al., 1990; Shimizu et al., 1990). Together, this evidence supports an intrastriatal mechanism for DA signal generation that can be initiated by excitatory inputs to the striatum that require glutamate and ACh. While cortically evoked DA signals in the striatum have been reported, identifying the unique pharmacological and basic properties of these input-specific signals will allow us to selectively manipulate and target them, leading to a better understanding of their functional significance. In this study, we tackle this gap in knowledge using both *in vivo* microdialysis and *in vitro* FSCV with optogenetic stimulation. Particularly, we set up a novel approach using dual optogenetic stimulation in the same brain slices to input-specific evoke DA release and compare the properties of these DA signals in the striatum.

Materials and Methods

Animals. All animals used in the study were maintained in accordance with the guidelines of the National Institutes of Health Animal Care, and the animal research procedures were approved by the National Institute on Alcohol Abuse and Alcoholism Animal Care and Use Committee for mice and by the National Institute on Drug Abuse Intramural Research Program Animal Care and Use Committee for rats. Except for the *in vivo* microdialysis experiments, all experiments were conducted using male and female mice of C57BL/6 background. Heterozygote B6.SJL-*Slc6a3*$^{tm1.1(cre)Bkmn}$/J mice (Backman et al., 2006) (The Jackson Laboratory, 006660) referred to as DAT$^{IRES\text{-}Cre+}$ mice and negative DAT$^{IRES\text{-}Cre-}$ littermates considered as WT mice were used. To fluorescently label CINs, homozygote B6N.129S6(B6)-*Chat*$^{tm2(cre)Lowl}$/J mice (Rossi et al., 2011) (The Jackson Laboratory, 018957) were crossed with homozygote B6.Cg-*Gt(ROSA)26Sor*$^{tm14(CAG\text{-}tdTomato)Hze}$/J mice (Madisen et al., 2010) (The Jackson Laboratory, 007914), and the progeny is referred to as CIN-tdTomato mice. For the microdialysis experiments, male Sprague Dawley albino rats (Charles River Laboratories) were used. Rats were housed individually for the first week after intracranial injection, until suture removal, after which the rats were housed 2 per cage. All animals were housed on a 12 h light/dark cycle (06:30 to 18:30 light) with food and water *ad libitum*.

Surgery and stereotaxic injection of AAV-ChR2 vectors. Injections were conducted as described previously (Adrover et al., 2014). Briefly, mice (5-6 weeks old) were anesthetized by inhalation of isoflurane-oxygen mixture and placed in a stereotaxic frame (David Kopf). Adeno-associated virus (AAV) vectors with Cre recombinase-dependent expression of Channelrhodopsin2 (ChR2) protein, AAV5-EF1a-DIO-hChR2(H134R)-EYFP (4×10^{12} IU/ml), were bilaterally injected into the VTA/SNc (AP: −3.30, ML: ±0.60, DV: −4.50) of DAT$^{IRES\text{-}Cre+}$ mice. The AAV vectors AAV5-CaMKII-hChR2(H134R)-EYFP (4×10^{12} IU/ml) or AAV5-Syn-ChrimsonR-tdTomato (1.7×10^{13} IU/ml), were injected in the PFC (PrL cortex, AP: 2.10, ML: ±0.35, DV: −2.30; IL cortex, AP: 1.90, ML: ±0.30, DV: −3.20) of negative littermates or DAT$^{IRES\text{-}Cre+}$ mice. All stereotaxic coordinates were from bregma (in mm) according to the mouse atlas by Franklin and Paxinos (2007); 300-500 nl for VTA/SNc and 100-200 nl for PFC were injected at a flow rate of 100 nl/min. Recordings were made after a minimum of 4 weeks of incubation. For mice injected in both VTA/SNc (DIO-ChR2-EYFP) and PFC (ChrimsonR-tdTomato), recordings were performed after a minimum of 8 weeks of incubation. Viral vectors were purchased from Gene Therapy Center Vector Core at University of North Carolina and Penn Vector Core at University of Pennsylvania.

Slice preparation. Mice were anesthetized and rapidly decapitated. Brains were quickly removed, mounted, and sliced using a vibratome (VT-1200S, Leica Microsystems) in an ice-cold cutting solution containing the following (in mM): 225 sucrose, 13.9 NaCl, 26.2 $NaHCO_3$, 1 NaH_2PO_4, 1.25 glucose, 2.5 KCl, 0.1 $CaCl_2$, 4.9 $MgCl_2$, and 3 kynurenic acid. The sagittal slices (240 μm) were incubated for 20 min at 33°C in ACSF containing the following (in mM): 124 NaCl, 1 NaH_2PO_4, 2.5 KCl, 1.3 $MgCl_2$, 2.5 $CaCl_2$, 20 glucose, 26.2 $NaHCO_3$, and 0.4 ascorbic acid, and kept in the dark at room temperature before use. Recording chamber was perfused at 2 ml/min with ACSF heated at 32°C using an inline heater (Harvard Apparatus).

FSCV and amperometry. FSCV was performed in the dorsal striatum. Carbon-fiber electrodes (CFEs) were prepared with a cylindrical carbon-fiber (7 μm diameter, ~150 μm of exposed fiber) inserted into a glass pipette. Before use, the CFEs were conditioned with an 8-ms-long triangular voltage ramp (−0.4 to 1.2 and back to −0.4 V vs Ag/AgCl reference at 400 V/s) delivered every 15 ms. CFEs showing current >1.8 μA or <1.0 μA in response to the voltage ramp at ~0.6 V were discarded. During the recording, the CFEs were held at −0.4 V versus Ag/AgCl, and the same triangular voltage ramp was delivered every 100 ms. DA transients were evoked by electrical or optical single pulse, or 5 pulses at 20 Hz stimulations. Using the same CFE and location, DA signals were evoked by alternating electrical and optical stimulations in some experiments. These data were combined with results from other experiments where either electrical or optical stimulation was used to evoke DA signals. For electrical stimulation, a glass pipette filled with ACSF was placed near the tip of the carbon fiber and a rectangular pulse (0.2 ms, 100 μA) was applied every 2 min. For optogenetic stimulation, a fiber-optic (200 μm diameter, 0.22 NA, ThorLabs) connected to a blue LED (470 nm, 1.8 mW of maximal output power measured at the tip of the fiber-optics, ThorLabs) was placed over the carbon fiber and light pulses (0.6 ms) were delivered every 2 min. For input-output curves, the widths of light pulse were 0.1, 0.2, 0.5, 1, 2, and 5 ms. For dual optogenetic recordings, two fiber-optics connected to a purple LED (420 nm, 3.0 mW, ThorLabs) and an orange LED (590 nm, 0.7 mW, ThorLabs), respectively, were placed over the carbon fiber. Light pulses (0.6 ms for 420 nm and 0.6-2 ms for 590 nm) were delivered in an alternating pattern every 2 min. Data were collected with a retrofit headstage (CB-7B/

EC with 5 MΩ resistor) using a Multiclamp 700B amplifier (Molecular Devices) after low-pass filter at 3 kHz and digitized at 100 kHz using a DA board (NI USB-6229 BNC, National Instruments). Data acquisition and analysis were performed using a custom-written software, VIGOR, in Igor Pro (Wavemetrics) using mafPC (courtesy of MA Xu-Friedman). The current peak amplitudes of the evoked DA transients were converted to DA concentration according to the postexperimental calibration using 1-3 μM DA. Amperometric recordings were performed using the same carbon-fiber electrodes held at −0.4 V versus Ag/AgCl and a 30-s-long step to 0.6 V was applied. Single pulse or 5 pulses at 20 Hz stimulation were delivered at 20 s after switching to 0.6 V. Since we did not find major differences between PrL and IL in evoking DA transients, we combined the data obtained from two groups to represent DA transients evoked by PFC inputs (PFC-oDA).

Cell-attached recordings. Striatal CINs from CIN-TdTomato mice injected with ChR2-EYFP in the PFC were identified by fluorescence and confirmed by their characteristic spontaneous firing pattern. Cell-attached recordings were performed from CINs in the striatum using glass pipette electrodes with a resistance of ~3-4 MΩ, filled with an internal solution containing the following (in mM): 120 cesium methanesulfonate, 20 CsCl, 10 HEPES, 0.2 EGTA, 10 sodium phosphocreatine, 4 Na2-ATP, and 0.4 Na-GTP, pH, 7.25 (290-310 mOsm), at a holding potential of 0 mV. To estimate the strength of connectivity to CINs, the lowest light intensity needed to reliably evoke action potentials in CINs was determined, ranging from 0.4 mW for "high" connectivity to 2.1 mW for "low" connectivity. The data were collected using a Multiclamp 700B amplifier after low-pass filter at 1 kHz and digitized at 5 kHz, using pClamp10 software (Molecular Devices). Spike fidelity was calculated as percentages of the number of AP evoked from five trials for both single pulse and trains stimulation.

In vivo *microdialysis and optogenetic stimulation of the cortical inputs.* Rats (80-90 g) received unilateral intracranial injection of AAV-CaMKIIa-hChR2(H134R)-EYFP (titer: 10^{12} IU/ml; Gene Therapy Center Vector Core at University of North Carolina) in the PrL and IL cortex (AP: 3.0 mm, ML: 0.5 mm, DV: −3.5 and −5 mm with respect to bregma). Two injection sites per hemisphere were used, and 300 nl of viral vector solution was delivered per site via a 105-μm-thick silica tubing injector coupled directly to a 1 μl syringe driven by an infusion pump (rate = 50 nl/min) during 10 min. The injector was left in place for an additional 10 min following each injection to allow for diffusion of the suspension. Ten weeks after viral vector injection, rats (350-400 g) underwent surgery for probe implantation according to previously published procedures (Quiroz et al., 2016). Briefly, a modified microdialysis probe with an embedded light-guiding optic fiber was implanted into the NAc shell (AP: 1.2 mm, ML: 0.5 mm, DV: −8.0 mm with respect to bregma). The probe was fixed to the skull with a stainless-steel screw and glass-ionomer dental cement. All surgical procedures were performed under anesthesia with 3 ml/kg of Equithesin (4.44 × *g* of chloral-hydrate, 0.972 × *g* of Na pentobarbital, 2.124 × *g* of $MgSO_4$, 44.4 ml of propylene glycol, 12 ml of ethanol, and distilled H_2O up to 100 ml of final solution; National Institute on Drug Abuse Pharmacy). To build the microdialysis probe with embedded optic fiber, the tip of an optic fiber (105 μm diameter core, 0.22 NA) was sculpted into a conical shape using a Flaming-Brown pipette puller fitted with a custom platinum heating filament (Sutter Instruments) to allow for a larger area of stimulation. The conical optic fiber tip was embedded inside the microdialysis probe and implanted. Microdialysis experiments were performed in freely moving rats 24 h after probe implantation. Optical fiber was coupled to a 473 nm solid-state laser module and light stimulation was driven by a Grass S88 stimulator. Light stimulation was delivered for 20 min as trains of light pulses (2 ms pulse duration; at 100 Hz for 160 ms; trains repeats once per second; intensity = 5-8 mW at probe tip). ACSF containing (in mM) 144 NaCl, 4.8 KCl, 1.7 $CaCl_2$, and 1.2 $MgCl_2$ was pumped through the optogenetic-microdialysis probe (rate = 1.25 μl/min). After a washout period of 90 min, dialysate samples were collected at 20 min intervals. After 80 min of baseline sampling, optogenetic stimulation was applied for 20 min, and samples were collected for 80 additional minutes after the end of the stimulation. Samples were split and analyzed separately for glutamate, DA, and ACh content. ACh and glutamate contents were measured by HPLC coupled to an ACh oxidase and glutamate oxidase enzyme reactors, respectively, and electrochemical detection (Eicom). DA was measured by HPLC coupled with a coulometric detector (5200a Coulochem III, ESA). At the end of the microdialysis experiment, animals were deeply anesthetized with Equithesin and perfused transcardially with 0.1 M PBS, followed by 4% formaldehyde in 0.1 M PBS, pH 7.4. Brains were postfixed in the same fixative for 2 h and immersed in 20% sucrose/0.1 M PBS, pH 7.4, solution for 48 h at 4°C. Forty-micron-thick coronal sections were cut in a Leica Microsystems CM3050S cryostat at −20°C, collected in PBS, and stored in antifreeze-buffered solution (20% ethylene glycol, 10% glycerol, and 10% sucrose in PBS) at −80°C until processing. Sections were then evaluated for localization of implanted probes and ChR2-EYFP expression. Wide-field images were acquired with a Typhoon laser scanner (GE Healthcare). Confocal fluorescence microscopy images were acquired with an Examiner Z1 microscope (Carl Zeiss) fitted with a confocal laser module (LSM-710, Carl Zeiss).

Drugs. Dihydro-β-erythroidine hydrobromide (DHβE) was purchased from Tocris. Kynurenic acid (sodium salt), NBQX, and 3-((*R*)-2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP) were purchased from Abcam. All other chemicals were purchased from Sigma Millipore.

Statistical analysis. Statistical analysis was performed with Prism (GraphPad). One-sample *t* test, two-tailed paired *t* test, repeated-measures one-way ANOVA with or without mixed-effects models, or two-way ANOVA was used as specified. Tukey's or Dunnett's multiple comparisons test was used for *post hoc* analysis as specified. The number of experiments, *n*, was expressed as the number of slices or cells/the number of mice or number of rats for the *in vivo* microdialysis experiments.

Results

In vivo stimulation of PrL/IL inputs increases striatal ACh and DA concentration, and the increase in DA requires nAChR activation

Published work *in vivo* shows that optogenetic stimulation of cortical inputs to the striatum can evoke DA release (Quiroz et al., 2016). However, this study provides no evidence that activation of these cortical inputs recruits striatal CINs or that the cortically evoked DA release *in vivo* requires activation of striatal nAChRs. To assess these matters, we used *in vivo* microdialysis combined with optogenetic stimulation, as previously described (Quiroz et al., 2016), and measured extracellular levels of ACh and DA in response to optogenetic stimulation of cortical inputs. A modified microdialysis probe with an embedded light-guiding optic fiber was implanted into the striatum of rats expressing ChR2-EYFP in the PrL/IL cortex (Fig. 1*A*,*B*). On the experiment day, dialysate samples were collected at baseline for 80 min before stimulation started. Optogenetic stimulation of cortical axons within the striatum was delivered around the microdialysis probe as trains of light pulses (16 pulses at 100 Hz every 1 s for 20 min). Samples were collected for an additional 80 min after stimulation and were split and analyzed separately for DA and ACh content or DA and glutamate. This long train of *in vivo* optogenetic stimulation of PrL/IL cortical axon fibers within the striatum produced an increase in extracellular concentration of DA in the striatal dialysate (185.1 ± 44.0% of baseline, $n = 7$; $F = 5.27$, $p = 0.0002$, repeated-measures one-way ANOVA; $p = 0.0002$ for 60 min vs 80 min; Dunnett's multiple comparisons test; Fig. 1*C*), which coincided with an increase of extracellular ACh concentration (196.7 ± 36.6% of baseline, $n = 7$; $F = 3.00$, $p = 0.0002$, repeated-measures one-way ANOVA; $p = 0.004$ for 60 min vs 80 min; Dunnett's multiple comparisons test; Fig. 1*D*). These *in vivo* microdialysis findings support the hypothesis that cortical stimulation recruits CINs. In addition, when the *in vivo* optogenetic stimulation was performed in constant perfusion of

the nAChR antagonist DHβE (10 μM) delivered locally via reverse dialysis, the same stimulation protocol did not cause any change in extracellular DA concentration in the striatal dialysates (96.5 ± 11.6% of baseline, $n = 9$; $F = 0.64$, $p = 0.70$, repeated-measures one-way ANOVA; Fig. 1*E*), indicating that activation of nAChRs in the striatum is required for the cortically evoked DA release *in vivo*. As a control, we measured glutamate concentration in these same dialysates, which showed increased glutamate levels and confirmed the delivery of cortical stimulation in the presence of the nAChR antagonist (184.3 ± 27.3% of baseline, $n = 9$; $F_{(6,45)} = 4.01$, $p = 0.003$, repeated-measures one-way ANOVA with mixed-effects model; $p = 0.0006$ for 60 min vs 80 min; Dunnett's multiple comparisons test; Fig. 1*F*).

Stimulation of PrL/IL inputs to striatum is sufficient to evoke local DA signals in brain slices

In order to precisely access the specific inputs and apply pharmacological agents, we used transgenic mice with combination of optogenetic stimulation. DA signals were recorded in the striatum using FSCV in mouse brain slice preparations. Release of DA from axonal projections within the striatum was evoked by electrical stimulation and compared with DA signals evoked by

input-specific optogenetic stimulation. To achieve input-specific stimulation, ChR2-EYFP was expressed in either midbrain DANs and their axonal projections to the striatum using Cre-dependent viral vector injection in $DAT^{IRES\text{-}Cre+}$ mice (Fig. 2*A*) or ChR2-EYFP in cortical neurons of the PrL/IL cortex and their projections to the striatum using viral injection in Cre-negative littermate mice (Fig. 2*B*).

As expected, single brief pulses of electrical stimulation delivered via an electrode placed within the striatal tissue reliably evoked DA (electrically evoked DA transient [eDA]) signals in striatal brain slices (Fig. 2*C*). Also, direct optogenetic stimulation of midbrain DAN axonal projections within the striatum also evoked DA signals (referred here as DAN-oDA) on delivery of a single brief pulse of blue light (0.6 ms), in agreement with

previous published studies (Adrover et al., 2014; Melchior et al., 2015). Last, similar to the *in vivo* findings in Figure 1, selective optogenetic stimulation of axon projections from PrL/IL cortex into the striatum was also sufficient to trigger DA signals (referred as PFC-oDA) in the striatum of in slice preparation (Fig. 2*C*). These PFC-oDA signals were also reliably evoked by brief single pulses of blue light (0.6 ms) in the ventral portion of the dorsomedial striatum in sagittal brain slices (Fig. 2*D*). The viral expression around injection site was often large enough to include both PrL and IL regions of the cortex. For this reason, we combined data from the two regions. It is worth noting that these brain sections mainly contain the axon projections from PrL/IL neurons, but not their cell bodies, which are localized to more medial sagittal sections of the brain (Fig. 2*B*, inset).

The current–voltage plots of DA signals evoked via the three different types of stimulation (electrical, optogenetic stimulation of DANs, and optogenetic stimulation of PrL/IL) were indistinguishable and displayed current peaks at the expected oxidation (0.56 ± 0.01 V for eDA, $n = 15/n = 8$; 0.58 ± 0.01 V for DAN-oDA, $n = 14/n = 6$; 0.56 ± 0.01 V for PFC-oDA, $n = 22/n = 13$; $F = 0.49$, $p = 0.62$, repeated-measures one-way ANOVA with mixed-effects model; Fig. 2*E*) and reduction voltages (-0.17 ± 0.01 V for eDA, -0.14 ± 0.01 V for DAN-oDA, -0.16 ± 0.02 V for PFC-oDA; $F = 0.76$, $p = 0.49$, repeated-measures one-way ANOVA with mixed-effects model; Fig. 2*E*) for DA. The peak amplitude of eDA was significantly higher than DAN-oDA or PFC-oDA (556 ± 42 nM for eDA; 367 ± 58 nM for DAN-oDA; 325 ± 23 nM for PFC-oDA; $F_{(2,12)} = 13.430.76$, $p > 0.05$, repeated-measures one-way ANOVA with mixed-effects model; $p = 0.01$ for eDA vs DAN-oDA, $p = 0.0005$ for eDA vs PFC-oDA, and $p = 0.99$ for DAN-oDA vs PFC-oDA; Tukey's multiple comparisons test; Fig. 2*F*), and the decay time constants (tau) were similarly longer with eDA (0.25 ± 0.01 s for eDA, 0.22 ± 0.01 s for DAN-oDA, 0.23 ± 0.01 s for PFC-oDA; $F_{(2,12)} = 13.43$, $p = 0.0009$, repeated-measures one-way ANOVA with mixed-effects model; $p = 0.004$ for eDA vs DAN-oDA, $p = 0.009$ for eDA vs PFC-oDA, and $p = 0.83$ for DAN-oDA vs PFC-oDA; Tukey's multiple comparisons test; Fig. 2*G*). Thus, we were able to reliably evoke steady DA signals by selective optogenetic stimulation of axon projections from PrL/IL cortex in the ventral portion of the dorsomedial striatum. The DA signals recorded using FSCV showed indistinguishable chemical and temporal characteristics, even when evoked by different inputs.

Unique physical and pharmacological properties across input-specific DA signals

We first explored the threshold for triggering the input-specific optogenetically evoked DA signals. The threshold was determined by constructing input-output curves and varying the light pulse durations from 0.1 to 5 ms in brain slices from mice expressing ChR2 in midbrain DANs or the PrL/IL region (Fig. 3*A*,*B*). The relative amplitudes of DA transients were overlapping for pulses of 0.5-5 ms duration, and both DAN-oDA and PFC-oDA signals showed maximal amplitude with 1-5 ms light pulse durations. However, very short light pulses (0.1 ms) evoked measurable DA signals only in slices in which ChR2 was expressed in midbrain DAN projections to the striatum, indicating a lower threshold for evoking DA signals with direct stimulation of DA neuron axons than with stimulation of cortical inputs (duration × input, $F_{(5,90)} = 11.58$, $p < 0.0001$, repeated-measures two-way ANOVA; *post hoc* for the duration of 0.1 ms: $33 \pm 4\%$ for DAN-oDA, $n = 12/n = 8$, and $1.9 \pm 0.7\%$ for PFC-oDA, $n = 8/n = 5$, $p < 0.0001$; Fig. 3*B*). A higher threshold for the cortically evoked DA signals could reflect technical differences, such as opsin expression levels, or other biological factors, such as the density of innervation of cortical versus DAN axonal projections, difference in the release probability of the DA varicosities that respond to direct stimulation of DAN axons from those responding to cortical inputs, and/or the indirect and polysynaptic nature of the cortical-evoked DA signals.

To determine whether PrL/IL activation elicits striatal DA release and engages the CIN-dependent mechanism as shown in *in vivo* microdialysis experiment (Fig. 1), we then studied the basic pharmacological characteristic of DA signals evoked by stimulation of PFC inputs and compared them with those evoked by electrical and DAN input stimulation. In striatal brain slices, PFC-oDA signals were completely abolished by a mixture of AMPA and NMDA receptor antagonists (NBQX/CPP), whereas eDA and DAN-oDA signals were unaffected (amplitude after the antagonists = $0.3 \pm 1.6\%$ of baseline for PFC-oDA, $n = 6/n = 5$; $107.3 \pm 3.0\%$ for eDA, $n = 6/n = 4$; $99.8 \pm 1.4\%$ for DAN-oDA, $n = 6/n = 4$; $F_{(2,3)} = 694.8$, $p < 0.0001$, repeated-measures one-way ANOVA with mixed-effects model; $p = 0.14$ for eDA vs DAN-oDA, p values < 0.0001 for PFC-oDA vs eDA or PFC-oDA vs DAN-oDA; Tukey's multiple comparisons test; Fig. 3*C*, *D*). These findings indicate a requirement for ionotropic glutamate transmission for PrL/IL inputs to evoke local DA signals, which is in agreement with previous reports on the requirement of glutamate transmission for DA signals evoked by motor cortex and thalamic inputs to the striatum (Threlfell et al., 2012; Kosillo et al., 2016; Cover et al., 2019). Further, similar to our *in vivo* data (Fig. 1*D*), DHβE also abolished PFC-oDA signals, and significantly depressed eDA signals, while having no effect on DAN-oDA signals ($1.9 \pm 1.4\%$ of baseline for PFC-oDA, $n = 11/n = 7$; $21 \pm 3\%$ for eDA, $n = 10/n = 5$; $99 \pm 3\%$ for DAN-oDA, $n = 5/n = 2$; $F_{(2,7)} = 395.2$, $p < 0.0001$, repeated-measures one-way ANOVA with mixed-effects model; $p < 0.0001$ for eDA vs DAN-oDA, $p = 0.0006$ for eDA vs PFC-oDA, and $p < 0.0001$ for DAN-oDA vs PFC-oDA; Tukey's multiple comparisons test; Fig. 3*E*,*F*). Together, the pharmacology results support the hypothesis that PFC-oDA signals are mediated by activation of glutamate synapses from PrL/IL cortex to striatal CINs, which excites them to fire and trigger ACh release, thereby driving DA release via activation of nAChRs on DAN axon fibers within the striatum.

ACh is rapidly cleared by enzymatic degradation by AChE (Quinn, 1987). The extremely dense presence of AChE in the striatum (Zhou et al., 2001) assures the termination of cholinergic action. We also have previously shown the influence of the AChE on the DA transmission in the striatum (Shin et al., 2015, 2017). As AChE activity shows temperature dependence (Vidal et al., 1987), we then tested the temperature dependence of the input-specific DA transients by varying the temperature of the bath solution. The amplitude of both DAN-oDA and PFC-oDA signals increased linearly as the temperature was lowered from the standard 32°C to 25°C, and both showed a tight negative regression with similar slopes significantly different from zero ($-10.8 \pm 0.6\%$ per °C, $n = 8/n = 3$, for DAN-oDA, and $-10.8 \pm 2.0\%$ per °C, $n = 6/n = 3$, for PFC-oDA; p values < 0.0001; Fig. 3*G*,*H*). The temperature dependence of the DA signal amplitude likely reflects the change in rate of DA transporter activity with temperature. DA transporter activity was reported to have a temperature coefficient Q_{10} ranging from 1.39 to 2.95 (Zhu and Hexum, 1992), from which we estimate a Q_{10} of ~2.3 for the DA transporter for 24°C–37°C range. Our estimate predicts that large changes in the rate of DA reuptake by the transporter would be around the tested and physiological temperatures.

Indeed, the decay of the DA transients, which is a parameter that reflects the clearance of extracellular DA by the transporter, was also affected as the temperature was lowered. The decay time constant of both DAN-oDA and PFC-oDA increased linearly with the decrease of the temperature (DAN-oDA: -0.017 ± 0.001 s/°C; PFC-oDA: -0.025 ± 0.001 s/°C; Fig. 3*I*), which corresponded with the linear increase in amplitude. However, raising the temperature from 33°C to 35°C caused a dramatic and selective drop in the amplitude of the PFC-oDA signals, compared with DAN-oDA signals (Fig. 3*G*,*H*). The slope for PFC-oDA signals increased threefold from −11% to −31% per °C.

Vidal et al. (1987) have reported on a high dependence with temperature of the activity of AChE from rat brain, which reaches maximal rate at ~35°C. Our *in vivo* and *in vitro* pharmacology experiments showed that PFC-oDA signals require activation of nAChR. Therefore, we speculate that the observed steep temperature dependence of the signals is in large part mediated by rate increase in AChE activity. Furthermore, at physiological temperatures, the PFC-evoked DA signals may be very localized near ACh release sites, presumably overlapping with nAChR expression in DAN axons.

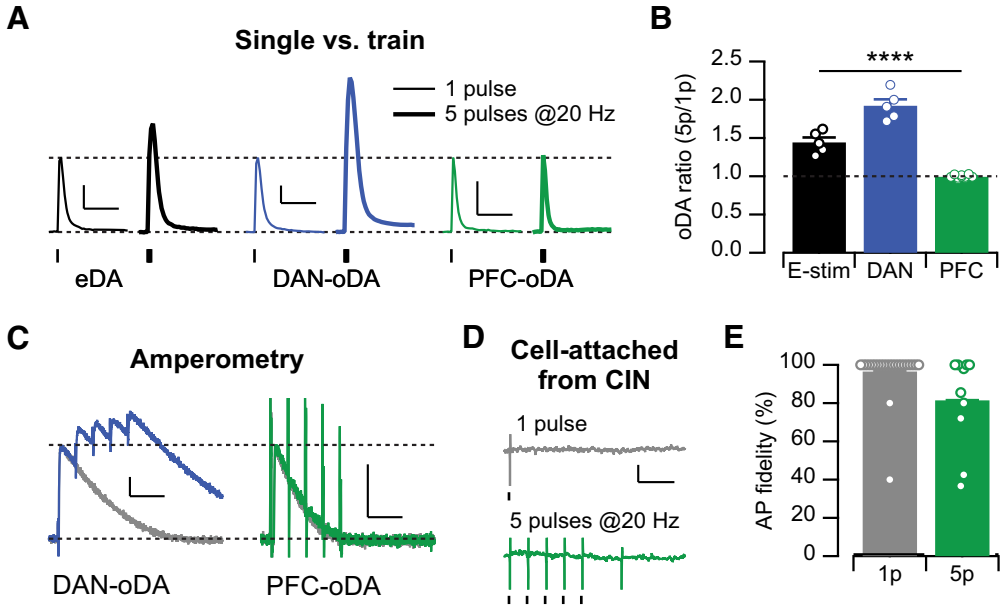

Figure 4. PFC-oDA shows no summation by train stimulations. ***A***, Representative DA traces of eDA, DAN-oDA, and PFC-oDA transients evoked by single pulse (1p, thin traces) or train of 5 pulses at 20 Hz (5p, thick traces). Scale bars: 200 pA, 100 ms. ***D***, Representative cell-attached recordings from CINs with single (top, gray) or train of 5 pulses at 20 Hz (bottom, green). Scale bars: 20 pA, 100 ms. ***E***, Averages with SEM of the action potential fidelity were plotted for the single pulse and train stimulation. Open circles represent individual values. ****$p < 0.0001$.

Activity dependent summation of the midbrain and cortical DA signals

Trains of stimulation pulses have been shown to produce sublinear summation in the amplitude of DA signals evoked by electrical and optogenetic stimulation of DAN axon projections in the striatum *in vitro* (Zhang and Sulzer, 2004; Threlfell et al., 2010; Melchior et al., 2015; Shin et al., 2017). We then tested the degree of summation of the DA signals in response to short trains of stimulation pulses (5 pulses at 20 Hz) and compared it with the transients evoked by a single pulse (Fig. 4*A*,*B*). This pattern of train stimulation was chosen based on burst firing patterns recorded *in vivo* for DANs during behavior (Schultz et al., 1993; Hyland et al., 2002). Indeed, we found that trains of 5 pulses at 20 Hz evoke DA transients 50% larger than those evoked by single pulse stimulation for eDA signals and almost double for DAN-oDA (5p/1p: 1.44 ± 0.06, $n = 5/n = 3$, for eDA; 1.92 ± 0.19, $n = 5/n = 2$, for DAN-oDA; 1.00 ± 0.02, $n = 10/n = 7$; $F_{(2,2)} = 110.6$, $p = 0.009$, repeated-measures one-way ANOVA with mixed-effects model; $p = 0.04$ for eDA vs DAN-oDA, $p = 0.03$ for eDA vs PFC-oDA, and $p = 0.008$ for DAN-oDA vs PFC-oDA; Tukey's multiple comparisons test; Fig. 4*A*,*B*). On the contrary, PFC-oDA transients evoked by this train stimulation had similar amplitudes compared with those evoked by a single pulse, indicating no summation of DA signals evoked by PrL/IL inputs. In order to measure DA signals with better temporal resolution, we performed amperometric recordings and again compared DA signals evoked by single pulse and trains (Fig. 4*C*). In line with the FSCV results, amperometric recordings showed that DAN-oDA signals display sublinear summation, whereas PFC-oDA signals are indistinguishable between single pulse or trains of 5 pulses at 20 Hz. The lack of summation in the PFC-oDA signals in response to trains resembles the findings obtained with DA signals evoked by synchronized activation of CINs (Threlfell et al., 2012; Shin et al., 2017) and further supports the idea that the PFC-evoked local DA signals are mediated by synchronized action of CINs in response to stimulation of PrL/IL inputs. The large transient current deflection in response to each pulse of stimulation ($n = 5/n = 4$; Fig. 4*C*, right) is suggestive of the action potential firing evoked in CINs and other striatal neurons by the optogenetic stimulation of PrL/IL inputs. The fact that every pulse of the train stimulation triggers a current deflection reflects the ability of PrL/IL inputs to evoke action potentials firing in downstream neurons and supports the idea that the lack of summation in DA signals is not likely because of the failure of action potential firing by CINs. To directly test the contribution of failure of action potential firing by CINs to the lack of summation in PFC-oDA signals, we conducted cell-attached recordings from CINs and measured action potential fidelity in response to a single pulse and trains of 5 pulses at 20 Hz (single pulse: $96.5 \pm 2.7\%$, $n = 23/n = 4$, $t = 1.28$, $p = 0.21$; trains of 5: $81.5 \pm 7.7\%$, $n = 10/n = 4$, $t = 2.42$, $p = 0.04$; both with one-sample t test to 100% value; Fig. 4*D*,*E*). Although there was a small but significant percentage of failure, the totality of the data indicates that the lack of summation is not likely caused by action potential failure, but instead can be attributed to other downstream mechanisms, such as desensitization of nAChRs (Threlfell et al., 2012; Shin et al., 2017).

Input-specific DA signals are evoked by dual optogenetic stimulation in the same brain slice

Thus far, DA signals evoked by the different inputs were recorded in brain slices from different mice that expressed ChR2 in either midbrain DANs or in PrL/IL cortex. In order to strictly test the segregation/distinction of these two pathways, it was important to examine these two inputs and compare the input-specific DA signals in the slice preparation from the same mice. We took advantage of opsins activated by different light wavelengths, specifically, ChR2 and the red-shifted opsin ChrimsonR

Figure 5. (Klapoetke et al., 2014). We first set up the conditions for selective stimulation of each opsin without cross-activation. In brain slices expressing only ChR2 in midbrain DANs, pulses of purple light (420 nm) evoked reliable DA signal, whereas similar and longer pulses of orange light (590 nm) did not trigger any detectable signals (Fig. 5*A*). Conversely, in slices expressing only ChrimsonR in the PrL/IL cortex, brief orange light pulses evoked DA signal, but not purple light (Fig. 5*B*). Thus, under these experimental conditions, ChR2 and ChrimsonR can be used in combination to selectively stimulate two different inputs by delivering pulses of two different light wavelengths without any detectable cross-activation.

Next, in the same $DAT^{IRES\text{-}Cre+}$ mice, ChR2-YFP was expressed in midbrain DANs with a Cre-dependent expression vector, and ChrimsonR-TdTomato was expressed in PrL/IL cortex. Figure 5*C* shows examples of the fluorescent expression pattern of ChR2-YFP (green) and ChrimsonR (red) in the same sagittal brain slice from this double-injected mouse. Figure 5*D* shows the experimental arrangement for the dual-input recordings with the placement of the carbon fiber and the two fiber-

optics for delivering the purple and orange light pulses that were used to activate ChR2 and ChrimsonR, respectively. In these slices with dual-opsin expression, brief pulses of either purple or orange light evoked DA signals with indistinguishable current–voltage plots, showing the characteristic peaks for DA oxidation and reduction (Fig. 5*E*). The DA concentration transients had comparable peak amplitudes with means of 407 ± 32 nM for DAN-oDA and 420 ± 36 nM for PFC-oDA ($n = 43/n = 13$, $t = 0.47$, df = 42, $p = 0.64$, paired t test; Fig. 5*F*) and overlapping time courses as measured at 10 Hz sample rate of FSCV, in agreement with the results shown in Figure 2. The decay time constant of the DA transients was similar (0.28 ± 0.01 s for DAN-oDA and 0.28 ± 0.01 s for PFC-oDA, $n = 43/n = 13$, $t = 0.41$, df = 41, $p = 0.68$ from paired t test; Fig. 5*F*).

Then, we tested the pharmacological properties of DAN-oDA and PFC-oDA by delivering alternating purple and orange light pulses and recording from a single carbon fiber. Application of the glutamate receptor antagonists NBQX/CPP (99.2 ± 3.1% of the baseline for DAN-oDA and 1.6 ± 1.1% for PFC-oDA, $n = 5/n = 3$; $t = 25.3$, df = 4, $p < 0.0001$, two-tailed paired t test; Fig. 5*G*) or the nAChR antagonist DHβE (101.9 ± 0.6% of the baseline for DAN-oDA and 0.8 ± 0.8% for PFC-oDA, $n = 5/n = 3$; $t = 79.13$, df = 4, $p < 0.0001$, two-tailed paired t test; Fig. 5*H*) completely abolished PFC-oDA signals while leaving DAN-oDA signals in the same location intact. These results confirm the findings from Figure 3, which use antagonists and single-input optogenetic stimulation to evoke either DAN-oDA or PFC-oDA in separate slices/mice. These results also validate the experimental approach by showing input specificity with no apparent crossover in the optogenetic stimulation of ChR2 and ChrimsonR with the described wavelengths. More importantly, these pharmacological findings highlight the different mechanisms and the unique nature of the input-specific DA signals evoked by PFC and midbrain inputs.

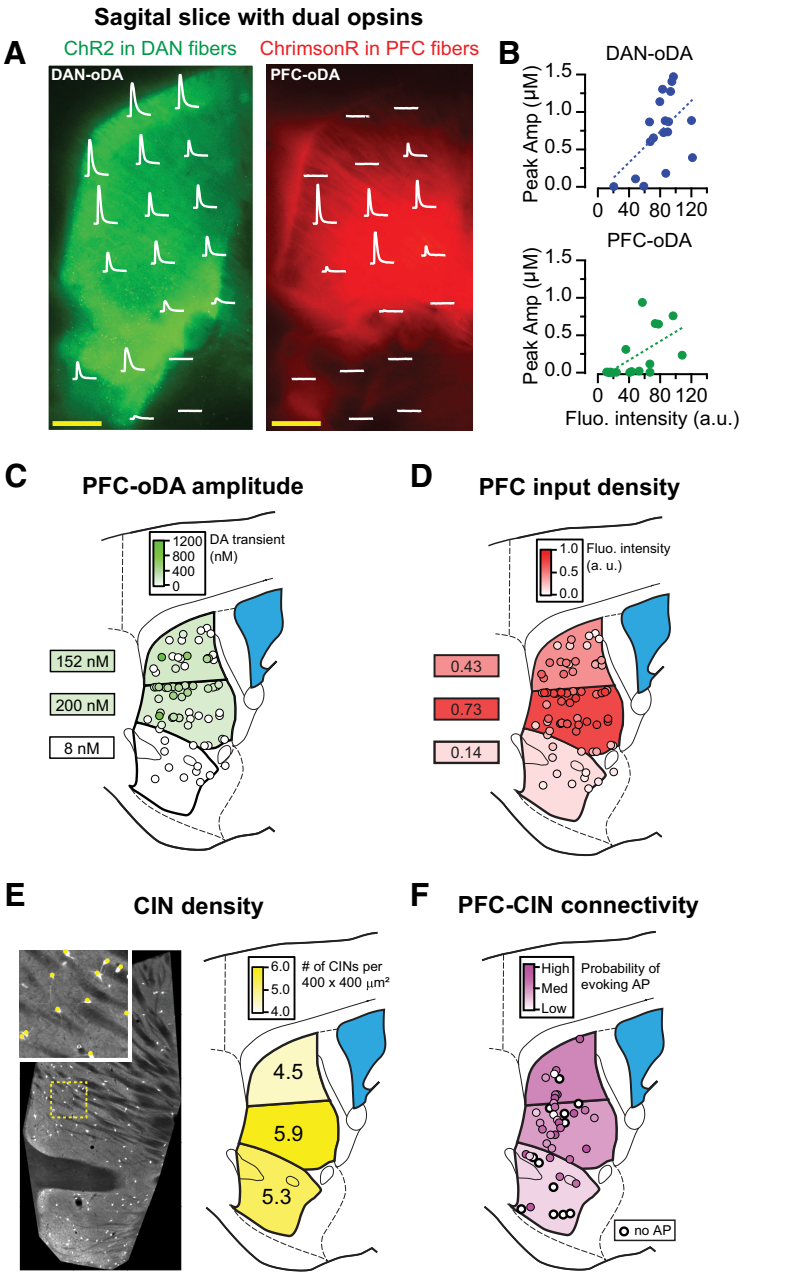

Figure 6. Cortically evoked DA signals are spatially restricted. ***A***, The locations of carbon fiber and two fiber-optics were adjusted to measure DAN-oDA (left) and PFC-oDA (right) from each location where the corresponding oDAs were superimposed on the fluorescence patterns. Scale bars, 500 μm. ***B***, Peak amplitudes of DAN-oDA (top) and PFC-oDA (bottom) were plotted as a function of florescence intensity at each location shown in ***A***. Dotted lines indicate linear regression between the oDA amplitudes and the fluorescence intensities. ***C***, PFC-oDAs were measured from 74 locations (between ~1.0 and 1.2 mm in mediolateral coordinate) of mice injected with ChR2-EYFP in PrL/IL cortex and color-coded according to their peak DA concentrations. The average PFC-oDA amplitudes were calculated and color-coded for the three subregions. ***D***, The PFC input fluorescence intensities were color-coded for the same 74 locations in ***C***. The averages from the three subregions were calculated and color-coded. ***E***, Left, Fluorescence image of striatal CINs labeled with td-Tomato. Inset, Examples of identified CINs (red) from the area with the dotted yellow line. Right, The average numbers of CINs per 400 × 400 μm^2 (area as shown in the inset) were calculated and shown for the three subregions. ***F***, Using cell-attached patch recording, action potentials evoked by PFC stimulation were observed from a total of 46 CINs. For each CIN, a minimum light intensity to evoke action potentials was determined to score the connectivity. White circles with a thicker line represent CINs which did not show any evoked action potentials even with the maximum light intensity.

Cortically evoked signals are spatially restricted

As shown in Figure 2*D*, DA signals evoked by selective stimulation of PrL/IL inputs were preferentially detected between the NAc core and dorsal striatum. We then set out to investigate in more detail the spatial distribution of the input-specific DA signals using the dual-opsin expression approach by sampling the amplitude of DA signals across 18 different striatal areas of the sagittal brain slice while evoking responses with purple and orange light. While DAN-oDA signals were detected throughout the whole striatum, PFC-oDA signals were spatially restricted (Fig. 6*A*,*B*). Both DAN-oDA and PFC-oDA signals showed significant correlations with the fluorescent intensity of the projections ($p = 0.03$ and $r^2 = 0.28$ for DAN-oDA; $p = 0.01$, $r^2 = 0.37$ for PFC-oDA; Fig. 6*B*). However, the slope of the linear regression was larger for DAN-oDA signals than PFC-oDA signals (10 vs 6

nM/AU, respectively; Fig. 6*B*). Thus, the intensity of the DAN-labeled fibers was a good predictor of the magnitude of DAN-oDA signals. On the other hand, the presence of cortical axon fluorescence was not always a predictor of PFC-oDA signals, likely because of the larger density of passing cortical axons that are not synaptic terminal run through the striatum.

Averaging the area responses in 5 brain slices from 3 mice, we found that the mean amplitude of the PFC-oDA signals was largest in the ventral part of the dorsal striatum, which again maps in gross terms with the location of the brightest intensity of ChR2-EYFP-labeled projections from PrL/IL cortex (Fig. 6*C*,*D*). However, the correlation between fluorescence intensity and amplitude of PFC-oDA signals is not always strong; for example, the more intensely labeled caudal areas near the globus pallidus show almost no PFC-oDA signal (Fig. 6*C*,*D*). The evidence of small or no PFC-oDA signals in the more caudal striatum could possibly reflect greater fiber density rather than innervation of the caudal portion of the striatum by the axonal projections from PrL/IL cortex.

The number of CINs is <1% of the total striatal neurons, and they are sparsely distributed throughout the striatum (Burke et al., 2017). We then quantified the density of CINs from the same area to further determine whether the distribution of CINs contribute to the spatial restriction of PFC-oDA signals. For this purpose, we took advantage of CIN-tdTomato mouse line, which fluorescently labels CINs throughout the striatal slices (Fig. 6*E*). The quantification analysis of cell numbers in 400×400 μm^2 showed that the density of CINs was also highest in the middle part of the dorsomedial striatum (6 slices from 3 mice), suggesting that an uneven distribution of CINs could also contribute to the spatial restriction of the local DA signals evoked by PrL/IL cortical inputs to the ventral portion of the dorsomedial striatum. To further test whether the spatial profile of PFC-oDA signals is in part determined by the strength of the innervation of CINs by PrL/IL cortical neurons, we performed cell-attached recordings from the same CINs of CIN-TdTomato mice and measured the ability of PFC optogenetic stimulation to evoke action potentials in CINs throughout the striatum (46 CINs from 3 mice). We found that the connectivity followed a similar pattern to the PFC-oDA profile, and the probability that CINs will fire an action potential in response to PFC stimulation was higher in the central part of the striatum than in the NAc and dorsal regions of the dorsal striatum (Fig. 6*F*).

In conclusion, this study offers a series of *in vitro* and *in vivo* evidence that stimulation of cortical inputs from the PrL/IL cortex can evoke DA release in the striatum via a local mechanism that recruits CINs and requires activation of nAChRs. Since these cortically evoked DA signals are spatially restricted and have different properties, we speculate that they are engaged in distinctive striatal functions from those assigned for DA signals evoked by midbrain DANs.

Discussion

This study provides strong evidence that DA signals in the striatum can occur both *in vivo* and *in vitro* in response to stimulation of PrL/IL cortical inputs. These PrL/IL-evoked DA signals have distinctive pharmacological and physiological properties, compared with the DA signals evoked by DAN inputs. The *in vitro* experiments also introduce a dual optogenetic stimulation approach with which we can activate two different inputs to the striatum in the same brain slice, without apparent cross-activation. This study further reveals the spatial localization of the DA signals evoked by PFC inputs.

We showed that the PrL/IL-evoked DA signals require activation of glutamate and nicotinic ACh receptors, in line of a series of elegant published work. Using *in vitro* radioactive assays and *in vivo* microdialysis, it was first shown that locally administered ACh and glutamate can trigger DA release in the striatum (Giorguieff et al., 1976, 1977). Giorguieff et al. (1976) showed that an nAChR antagonist blocked ACh-evoked DA signals, and speculated that ". . . the release of DA from dopaminergic terminals can be regulated by cholinergic presynaptic receptors exhibiting nicotinic characteristics." To their credit, their conclusions agree with our interpretations of the findings from the current study as well as other recent optogenetic studies where it was shown that selective stimulation of CINs is sufficient to evoke DA signals (Cachope et al., 2012; Threlfell et al., 2012; Wang et al., 2014; Shin et al., 2017). The involvement of CINs in the glutamate-dependent DA signals was also suggested by early work by Taber and Fibiger (1994) who showed that electrical stimulation of PFC can increase levels of ACh in the striatum and further supported by more recent optogenetic studies (Threlfell et al., 2012; Kosillo et al., 2016; Johnson et al., 2017; Mateo et al., 2017; Cover et al., 2019).

Here, our experiments confirmed the requirement for ionotropic glutamate receptor activation in the PFC-evoked DA signals as previously shown (Mateo et al., 2017). We also show that nAChRs are required for the PrL/IL-evoked DA signals *in vitro*, similar to other findings when stimulating inputs from other cortical (Kosillo et al., 2016) and thalamic areas (Threlfell et al., 2012; Kosillo et al., 2016; Cover et al., 2019) and indirectly *in vivo* (Mateo et al., 2017). Our results from the *in vivo* microdialysis experiments reproduce the original findings from Quiroz et al. (2016) showing that optogenetic stimulation of PFC inputs increases striatal levels of DA *in vivo* (and glutamate, as expected; Fig. 1). More importantly, we showed that stimulation of PrL/IL inputs to the striatum also elevates striatal levels of ACh *in vivo* and that this cortically evoked DA signals are blocked when a nAChR antagonist is perfused (Fig. 1*C*,*D*). Thus, these findings support that idea PrL/IL inputs form excitatory synapses on striatal CINs and can activate then to evoke ACh release (Fig. 1*C*). In agreement with this conclusion, recent work showed that optogenetic stimulation of either M1 motor cortex or parafascicular nucleus of the thalamus can induce release of ACh that was detected using exogenous G-protein-coupled inward rectifying K-current expressed in medium spiny neurons (Mamaligas et al., 2019). Together, our findings from both *in vitro* and *in vivo* strongly support the hypothesis of a local mechanism for evoking DA release in the striatum, in addition to the more conventional mechanism based on midbrain DAN firing. This local mechanism engages striatal CINs, the targets of inputs from PFC, which have an essential role in evoking DA release from DAN fibers.

DA signals evoked by PrL/IL inputs and those evoked by DAN fibers stimulation share common properties, such as overlapping electrochemical profiles of the voltammetric currents and similar concentration range, time course, and decay time constant of the signals (Figs. 2, 5*E*,*F*). However, there are also several differences between the input-specific DA signals. First, DAN-evoked DA signals do not require activation of either ionotropic glutamate receptors or nAChRs (Figs. 3*C*–*F*, 5*G*,*H*), confirming the direct nature of this mechanism that is triggered by ChR2-evoked action potentials in DAN axon fibers. Second, PrL/IL-evoked DA signals display different temperature

sensitivity and a higher threshold compared with DAN-oDA, requiring a longer duration of light stimulation as determined in the input-output relationship (Figs. 3, 4). This finding may reflect the polysynaptic nature of the cortically evoked signals and the requirement of synchronized activation of CINs to trigger DA release by this local mechanism (Threlfell et al., 2012; Kosillo et al., 2016; Liu et al., 2018). Third, the amplitude of DAN-evoked DA signals increases as the number of stimulation pulses increases, indicating some summation in the DA signals evoked by a train of stimulation pulses (Fig. 4*A*,*B*). In contrast, the amplitude of DA signals in response to a train of pulses of cortical input stimulation is similar to the amplitudes obtained in response to a single pulse of stimulation, indicating no summation under this condition for the local mechanism (Fig. 4*A*,*B*). ChR2 displays use-dependent inactivation when stimulated at high frequency (Hass and Glickfeld, 2016). However, the lack of summation by the train stimulation is unlikely because of this use-dependent inactivation of ChR2 since 20 Hz train stimulation was still able to evoke action potentials in CINs recorded in cell-attached mode (Fig. 4*D*,*E*) and amperometry recording showed large deflections in response to train stimulation (Fig. 4*C*). Anecdotally, these current deflections disappeared when the ionotropic glutamate receptor antagonists were applied, also supporting the idea that firing in CINs and other downstream neurons occurs in response to 20 Hz train stimulation. The lack of summation was also reported in DA signals evoked by direct optogenetic stimulation of CINs in the dorsal striatum (Threlfell et al., 2012; Shin et al., 2017), which was suggested to be because of nAChR desensitization. We speculate then that the lack of summation we report here by 20 Hz trains in PrL/IL-evoked DA signals, which also require nAChRs activation, is also because of desensitization.

To directly study and compare the input-specific DA signals in the same animal, we established dual optogenetic stimulation using a red-shifted opsin, ChrimsonR, in combination with the blue-light activated ChR2. Two wavelengths for excitation were chosen based on the excitation spectrum of each opsin (Klapoetke et al., 2014), 590 nm for ChrimsonR and 420 nm for ChR2, which showed no cross-activation (Fig. 5*A*,*B*). This dual optogenetic approach was further validated using pharmacology in animals expressing ChR2 in midbrain DANs and ChrimsonR in PrL/IL neurons. We found that PrL/IL-evoked DA signals were completely blocked by antagonists of either ionotropic glutamate receptors or nAChRs, without affecting DAN-oDA signals in the same slice (Fig. 5*G*,*H*). Therefore, we determined that the two inputs can be activated independently using this dual optogenetic approach in brain slices from the same animal.

Interestingly, using this dual optogenetic approach, an intriguing spatial pattern was revealed for the cortically evoked PrL/IL DA signals. While DAN-oDA signals were recorded throughout the striatum, PrL/IL oDA signals were spatially restricted to a "hot-spot" region around the boundary between the NAc core and dorsal medial striatum (Fig. 6). This hot-spot area for the PrL/IL oDA signals corresponds to the same area where we found the highest density of CINs in our analysis. Thus, CIN density could contribute in part to the generation of this hot-spot area for the PrL/IL-evoked DA signals. Further, we also found that this area has the highest intensity of fluorescently labeled PrL/IL fibers, as well as the highest degree of synaptic connections to CINs, which is also in agreement with reported patterns of cortical connectivity (Voorn et al., 2004). Our initial interest was to study the PFC projections to the accumbens. However, since PrL/IL-evoked DA signals were largest and more reliable in the ventral DS (Fig. 6), recordings were performed in this area. Together, these findings suggest that PrL/IL inputs and the synaptic innervation to CINs are preferentially localized to the dorsomedial subregion, giving rise to the largest cortically evoked DA signals.

From the mechanism described here for this PrL/IL-evoked DA signals, we propose that any input to the striatum that strongly activates CINs (cortical, thalamic, or any other brain region) can in theory evoke local DA signals in the striatum. We also speculate, based on ours and other groups' works, that these glutamate-driven DA signals can similarly happen in other striatal subregions. The selective localization of PrL/IL-evoked DA signals suggests the existence of a "topographic map" for the local DA signals where inputs from different cortical subregions can trigger local DA signals at the striatal subregion which they innervate. Spatial segregation of input-specific DA signals in the striatum is a new concept introduced here that is rarely considered in the field. This concept may become helpful in understanding how DA signals in the striatum can be involved in so many diverse processes ranging from reinforcement learning and motivation to motor output and action selection.

Processing of nonverbal social cues (NVSCs) is essential to interpersonal functioning and is particularly relevant to models of social anxiety. This article provides a review of the literature on NVSC processing from the perspective of social rank and affiliation biobehavioral systems (ABSs), based on functional analysis of human sociality. We examine the potential of this framework for integrating cognitive, interpersonal, and evolutionary accounts of social anxiety. We argue that NVSCs are uniquely suited to rapid and effective conveyance of emotional, motivational, and trait information and that various channels are differentially effective in transmitting such information. First, we review studies on perception of NVSCs through face, voice, and body. We begin with studies that utilized information processing or imaging paradigms to assess NVSC perception. This research demonstrated that social anxiety is associated with biased attention to, and interpretation of, emotional facial expressions (EFEs) and emotional prosody. Findings regarding body and posture remain scarce. Next, we review studies on NVSC expression, which pinpointed links between social anxiety and disturbances in eye gaze, facial expressivity, and vocal properties of spontaneous and planned speech. Again, links between social anxiety and posture were understudied. Although cognitive, interpersonal, and evolutionary theories have described different pathways to social anxiety, all three models focus on interrelations among cognition, subjective experience, and social behavior. NVSC processing and production comprise the juncture where these theories intersect. In light of the conceptualizations emerging from the review, we highlight several directions for future research including focus on NVSCs as indexing reactions to changes in belongingness and social rank, the moderating role of gender, and the therapeutic opportunities offered by embodied cognition to treat social anxiety.

Keywords: social anxiety, non-verbal behavior, social rank, dominance, affiliation, production, expression

INTRODUCTION

Individuals with social anxiety disorder (SAD) suffer from significant functional impairment in multiple aspects of daily life: Their academic trajectory is frequently interrupted, they are employed below potential, and their social functioning suffers (Stein and Kean, 2000; Eng et al., 2005; Aderka et al., 2012). Individuals who are high in social anxiety perceive themselves as submissive and behave in nonassertive ways (Aderka et al., 2009; Schneier et al., 2009; Weeks et al., 2011). Moreover, social anxiety has been associated with lower reported quality of intimacy in peer, friendship, and romantic relationships (Rodebaugh, 2009; Cuming and Rapee, 2010; Weisman et al., 2011). Detailed analyzes of interpersonal behavior suggested that individuals with high social anxiety appear less confident, less affiliative, and less synchronous in social interactions than individuals with low social anxiety (e.g., Fydrich et al., 1998; Kachin et al., 2001; Alden and Taylor, 2004).

In this article we examine difficulties in interpersonal communication in social anxiety from the perspective of functional analysis of human sociality (e.g., Bugental, 2000). From this perspective, each individual participates in several evolutionarily shaped social structures. The two most prominent structures are affiliative relationships (friendship, companionship, intimacy) and hierarchical relationships (authority, social rank, social power). The need to affiliate with or belong to a social group is considered one of the central social motives across species, and basic psychological systems are hypothesized to constantly monitor for inclusionary status (e.g., Baumeister and Leary, 1995). Similarly, a need to advance in the social hierarchy and to be sensitive to threats to one's status within a group appears to be inherited from our primate ancestors (Sapolsky, 2005). Social exclusion (i.e., ostracism or social rejection) and social submission (e.g., being defeated) threaten one's belonging to and standing in a social group. Such events also decrease one's chances of future social effectiveness and collaboration. In contrast, social acceptance and social ascendance increase one's chances of social flourishing. In the following, we review some evidence that social rank and affiliation are basic psychological systems and then we examine their links with nonverbal social cue (NVSC).

SOCIAL RANK BIOBEHAVIORAL SYSTEM (SRBS)

A distinctive feature of social species' cooperative living is the formation of dominance hierarchies (e.g., Rowell, 1974). Conspecific members of the species face competition for resources, leading to aggressive interactions (West-Eberhard, 1979). Social hierarchies afford dominant members privileged access to food and mates, thereby conferring survival advantages. Such hierarchies are social systems containing an "implicit or explicit rank order of individuals or groups with respect to a valued social dimension" (Magee and Galinsky, 2008, p. 354). Social hierarchies contribute to stable social organization, and this stability reduces the costs of social competition for both dominant and subordinate members (e.g., Sloman and Armstrong, 2002). Possibly due to its importance for survival, a specialized biobehavioral system that monitors for social rank appears to have developed in humans and other mammals. This biobehavioral system has been called the rank regulation system (Zuroff et al., 2010), hierarchical domain (Bugental, 2000), power (Shaver et al., 2011), or dominance behavior system (Johnson et al., 2012).

The Social rank biobehavioral system (SRBS) is postulated as constantly monitoring one's standing in relation to others and using that information to guide behavior (e.g., Silk, 2007). Neuroimaging evidence supported the role of limbic, prefrontal, and striatal pathways (Beasley et al., 2012) and possibly intraparietal sulci (Chiao et al., 2009) in human social rank processing. Moreover, individual differences in social rank were linked to neural activation of limbic and frontal pathways when viewing social information (e.g., Muscatell et al., 2012). The most frequently studied SRBS-related biochemical substrate has been testosterone (e.g., Schultheiss and Wirth, 2008). Testosterone was found to correlate with self-report, observational, and cognitive measures of dominance in men and women alike (e.g., Archer, 2006; Sellers et al., 2007); additionally, estradiol correlated with dominance in females (e.g., Stanton and Schultheiss, 2007).

SRBS appears to emerge early in the developmental sequence (Thomsen et al., 2011), to operate automatically (Moors and De Houwer, 2005; Tracy et al., 2013) and fluently (Zitek and Tiedens, 2012), and to be specifically attuned to certain nonverbal signals such as gaze, voice, gestures, and postures (Wolff and Puts, 2010; Terburg et al., 2012; Tracy et al., 2013). Thus, SRBS is postulated to organize and orchestrate individuals' responses to changes in social standing.

AFFILIATION BIOBEHAVIORAL SYSTEM (ABS)

Over the course of human evolutionary history, members of the same species depended on each other for survival. In humans and other mammals, individuals who could gather support from their social surroundings gained access to more resources and therefore increased their chances of survival and reproduction. Like the dominance system, affiliative system is another basic biobehavioral system which continuously monitors for inclusionary status (Baumeister and Leary, 1995). Indeed, failing to satisfy the need to belong was found to activate neural circuits that partially overlap those of physical pain (e.g., Eisenberger et al., 2003; Dewall et al., 2010). Specifically, social exclusion was associated with greater activity in dorsal anterior cingulate cortex (dACC) and anterior insula. Again, individual differences in sensitivity to social exclusion (such as rejection sensitivity and attachment anxiety) were associated with greater responses in these regions (Linnen et al., 2012). Oxytocin and vassopressin, neuropeptides germane to affiliative behavior, may be implicated in the regulation of interpersonal stress (Taylor et al., 2000) and as affecting prosocial behavior (Poulin et al., 2012). Relatedly, intranasal administration of oxytocin reduced distress following social rejection in women who endorsed emotional coping strategies (Cardoso et al., 2012). Moreover, oxytocin administration increased prosocial behavior in women with a history of positive parenting (Riem et al., 2013). ABS emerges early in the developmental sequence (Feldman, 2012), operates automatically (Lakin et al., 2008), and is attuned to nonverbal signals of touch, gaze, and vocalization (Guastella et al., 2008; Dunbar and Abra, 2010; Farley et al., 2013).

Some convergence exists at the conceptual level between the close social bonds system and the belongingness system. In general, the jury is still out whether these two systems are best conceptualized as distinct (e.g., Panksepp and Watt, 2011), or form a single coherent unit (e.g., Feldman, 2012). For purposes of this review we focus on their similarities and view them as one. Thus, we see the ABS as organizing and orchestrating individuals' responses to opportunities to, and ruptures in, social bonds.

SOCIAL RANK, AFFILIATION, AND NONVERBAL SOCIAL CUES (NVSCs)

Consistent evidence showed that social rank is more frequently expressed through nonverbal than verbal cues (e.g., Argyle et al., 1970; Mehrabian, 1970; Mignault and Chaudhuri, 2003). Moreover, when both verbal and nonverbal cues of social rank were present, nonverbal cues were more likely to influence observers' judgments than verbal ones (e.g., Argyle et al., 1970; Jacob et al., 2012). Similarly, affection is also frequently expressed via nonverbal cues such as touch, vocalization, and gaze (e.g., Feldman and Eidelman, 2007; App et al., 2012; Farley et al., 2013). Indeed, people communicate emotions through multiple nonverbal channels such as face, body, voice, and touch (e.g., Buck, 1984).

Communication efficacy has been shown to vary across nonverbal channels in accruing information about likability, dominance, and trustworthiness (e.g., Zuckerman and Driver, 1989; Hall et al., 2005; Todorov et al., 2009, 2013). Researchers posited that information encoded in postures and voices is transmitted more effectively to larger audiences across longer distances, such as to one's social group or across social groups, whereas information encoded in face and touch is more effectively transmitted to proximate others (Tracy and Robins, 2004; App et al., 2012). Correspondingly, social status emotions (such as pride or shame) were shown to be communicated more effectively through the body than through face or touch (App et al., 2012). Moreover, vocal information was found to effectively communicate dominance (Wolff and Puts, 2010), and research on animal and human behavior alike has documented strong links between expansive body postures and trait and state dominance (Weisfeld and Beresford, 1982; Ellyson and Steve, 1985; Hall et al., 2005). Indeed, Stanton et al. (2010) have postulated that the meaning of nonverbal signals as motivated and rewarding for the sender and the perceiver, respectively. Altogether, different lines of research converge in suggesting that: (a) NVSCs are uniquely suited to rapid, effective transmission of emotional, motivational, and trait

information and (b) various channels differ in their effectiveness for transmitting this information.

SOCIAL ANXIETY AND NONVERBAL SOCIAL CUES (NVSCs)

To date, the main nonverbal signal examined in the social anxiety context was emotional facial expression (EFE; see Staugaard, 2010 for reviews). There are sound theoretical reasons to focus on EFEs. First, facial affect is instrumental in social development, emotion regulation, and social functioning (e.g., Leppänen and Hietanen, 2001). Second, facial affect is processed by specialized networks within a particular circuit of brain structures, some of which function abnormally in social anxiety (Nakao et al., 2011). Third, as argued by Bistricky et al. (2011), direct gaze can initiate automatic self-referent processing and self-relative-to-other processing (e.g., "Is his response to me unfavorable?"), and these processes are known to be problematic in social anxiety. Fourth, facial affect represents particularly salient information in close interpersonal situations (App et al., 2012).

Other NVSCs share several important characteristics with EFEs. First, NVSCs are mostly involuntary. As a result, they are more likely to serve as "honest signals" of individuals' internal emotions or attitudes toward an interaction partner than more strategically controlled verbal content. Correspondingly, social information processing should be better attuned to NVSCs than to verbally communicated interpersonal information (e.g., Gotlib et al., 2004). Thus, NVSCs may offer more "privileged" access to individuals' formation of approach and avoidance tendencies than would verbal expressions. Second, inasmuch as emotions are preparatory states for action, perceiving NVSCs should prime an immediate social reaction (Frijda, 1986). Indeed, some suggested that NVSCs may constitute a more evocative medium of transmitting emotions than verbal information (Buck and Vanlear, 2002). Third, given the primacy of NVSCs in the developmental sequence, they likely form the foundation for affective sensitivity and regulation (Cozolino, 2002). The preverbal foundation of implicit affective memories has been assumed to form a lasting basis for self and other schemas (e.g., Bistricky et al., 2011).

Although examinations of EFE processing have extended and deepened understanding of social anxiety's basic processes and biases, much may be learned from expanding the framework in two ways. First, the inclusion of new signals and modalities—especially posture and voice—may elucidate how socially anxious individuals process interpersonal information and engage in impression formation and revision. In the following, we seek to summarize the rather disperse literature on NVSC processing in social anxiety, supplementing it with the burgeoning literature on voice and posture processing among nonclinical populations.

Second, we seek to expand the established framework by highlighting the important yet relatively understudied area of NVSC expression. Thus far, the vast majority of studies have examined biases in perception of NVSCs. However, the expression (or production) of those cues is central to interpersonal behavior and may provide an unbiased measure of the expresser's emotional states and interpersonal tendencies and abilities. Moreover, expression of these cues may, in itself, affect the expresser's cognitive and emotional states, thereby attenuating or intensifying those states (e.g., Carney et al., 2010). Consequently, we will review literature on facial, vocal, and postural expression in social anxiety and nonclinical populations.

ORGANIZATION OF THE REVIEW

This review has three broad goals. First, we aim to systematically review empirical studies examining NVSC perception in social anxiety. We focus mostly on research that employed information-processing approaches while incorporating pertinent cognitive neuroscience findings. Specifically, we review findings on perception of faces (including gaze orientation), voices, and bodies (postures and gestures). Second, we aim to review literature on NVSC production. Here we concentrate on mimicry of facial expression, eye gaze, vocal productions, and adoption of posture and body movements. Due to the paucity of research on some of these topics, we will draw on research with normal populations. Third, we aim to integrate these findings with the three prominent theories of social anxiety, and to formulate new testable hypotheses that may contribute to better understanding of this condition's basic underlying mechanisms.

PERCEPTION OF NONVERBAL SOCIAL CUES (NVSCs)

Theoretical accounts converge in suggesting that misinterpretations of neutral or affiliative social signals as threatening are likely to deepen distress and contribute to the maintenance of SAD (e.g., Clark and Wells, 1995; Rapee and Heimberg, 1997; Gilbert, 2001; Alden and Taylor, 2004; Hofmann et al., 2004). Consequently, enhanced understanding of factors that influence biased or inaccurate interpretations of NVSC signals may help formulate a more complete, accurate model of SAD. We review available evidence of biases in processing of cues from faces, voices, and bodies. For each channel, we first review the perception of emotional stimuli (i.e., emotional facial expression, prosody, emotional gestures), followed by a review of impression formation from stable cues (e.g., facial features, basic vocal and body characteristics) and integrated nonverbal representations.

FACES

Emotion facial expression (EFE)

We first review studies focusing on EFEs with direct gaze and then studies involving variations in gaze direction.

Attention. In a comprehensive review, Staugaard (2010) concluded that biased processing of threatening vs. neutral or smiling EFEs tended to emerge mostly under conditions of brief exposure and to disappear when exposure time increased. Staugaard's review, which included mostly studies of EFE processing in non-stressful conditions, yielded only elusive differences between individuals with high vs. low social anxiety in attentional processing of threatening EFEs. Overall, eye-tracking studies found that social anxiety tends to correlate with biased attention to threatening as well as smiling EFEs. In fact, several studies found that socially anxious individuals exhibited reduced total fixation time to all emotional stimuli (e.g., Chen et al., 2012). Moreover, although highly socially anxious individuals revealed difficulty disengaging from threatening faces (e.g., Buckner et al., 2010; Moriya and Tanno, 2011; Schofield et al., 2012), they also exhibited slower attentional disengagement

from smiling, as compared to neutral, faces (Gilboa-Schechtman et al., 1999). However, using a continuous flickering paradigm, Wieser et al. (2011) found that angry compared to smiling and neutral expressions were associated with greater electrocortical facilitation over visual areas in individuals with high social anxiety, but not in those with low social anxiety.

Kolassa and Miltner (2006) found that angry expressions during an emotion identification task elicited enhanced right temporoparietal N170 in individuals with SAD (Kolassa and Miltner, 2006) and in subclinically socially anxious individuals (Mühlberger et al., 2009). The research team also reported generally enhanced P100 amplitudes both in individuals with SAD and with other anxiety disorders (Kolassa et al., 2007). However, amplitudes of the N170 component and later event related potentials (ERP) components did not differ between SAD, spider phobic, and control participants when schematic emotional faces were presented (Kolassa et al., 2007) or with morphed expressions (Kolassa et al., 2009). Recently, Peschard et al. (2013) identified an enhanced P1 component in processing emotional and neutral faces in social anxiety. Combined, these data suggest that social anxiety may be related to a specific temporal pattern in processing naturalistic facial expressions.

Using fMRI, several studies employing block-designs found enhanced amygdala reactivity to angry faces (Stein, 2002; Straube et al., 2005; Phan et al., 2006; Evans et al., 2008), neutral faces (Birbaumer et al., 1998; Veit et al., 2002), and happy faces (Straube et al., 2005), pointing to hyperactivation of this area in social anxiety for all emotional expressions. Furthermore, researchers suggested that amygdala activation in highly socially anxious individuals may depend more on EFE intensity than on the particular emotion expressed (Yoon et al., 2007).

Altogether, these studies suggest that individuals high in social anxiety exhibit enhanced processing of all facial expressions in some tasks, disengagement difficulties from both threatening and smiling expression (as compared to neutral expressions) on other tasks, and enhanced vigilance/reactivity to angry expression on select tasks.

Interpretation and evaluation. Many studies found no association between social anxiety and labeling accuracy in emotional labeling tasks, especially when participants had unlimited time for completion (e.g., Joormann and Gotlib, 2006; Arrais et al., 2010; Campbell et al., 2009; Heuer et al., 2010). Similarly, several rating studies did not identify differences between individuals with high vs. low social anxiety in evaluating single discrete EFEs (Stein et al., 2002) or mixed displays of smiling, neutral, and angry expressions (Gilboa-Schechtman et al., 2005; Lange et al., 2011). Other studies that examined response latencies to morphed or degraded presentations of emotional expressions typically showed that social anxiety correlated with a lower threshold for identifying angry expressions (e.g., Joormann and Gotlib, 2006; Gilboa-Schechtman et al., 2008). Recently, Arrais et al. (2010) reported that, compared to women low in social anxiety, women high in social anxiety (but not men) required less emotional information to identify smiling, sad, and fearful expressions. Interestingly, when time constraints were introduced in labeling studies, biased interpretation/evaluation of EFEs emerged (e.g., Heuer et al., 2010). In addition, Heuer et al. (2007) found that, as compared to low socially anxious individuals, high socially anxious individuals showed stronger avoidance tendencies of smiling and angry faces, while no such differences with respect to neutral faces were identified. Combined, these studies suggest that persons with high social anxiety tend to exhibit more negative evaluations of ambiguous or smiling EFEs, either on implicit evaluation tasks, or under conditions of high task difficulty. Additionally, when rating studies required participants to engage in impression formation or in predicting emotional impact of possible interactions, persons with high social anxiety rated smiling faces as less approachable and angry faces as more costly (e.g., Campbell et al., 2009; Douilliez et al., 2012).

Memory. The social anxiety literature is mixed regarding memory biases for experimentally presented stimuli. Some studies documented enhanced processing of threatening stimuli (e.g., Foa et al., 2000), whereas others found no such biases (e.g., Rapee et al., 1994; Coles and Heimberg, 2002; Rinck and Becker, 2005 for reviews). Other studies supported the erosion of positive memory biases in SAD (Liang et al., 2011). In general, however, the support is rather modest for negative memory bias or diminished positive bias in SAD using EFEs.

Gaze direction

Eye gaze plays an essential role in social interactions, as averted gaze may relay various social intentions such as submission (Mazur and Booth, 1998), disinterest (Itier and Batty, 2009), or even rejection (e.g., Wirth et al., 2010). Generally, direct gaze (vs. averted) was linked with observers' higher levels of physiological arousal (i.e., skin conductance), an effect enhanced for smiling faces (Pönkänen and Hietanen, 2012). In another study, participants rated averted gaze as less pleasant than direct gaze (Schmitz et al., 2012). In a virtual reality study, women high in social anxiety exhibited greater increase in avoidance while responding to male avatars when avatars had direct gaze than averted gaze while women with low social anxiety did not exhibit this pattern (Wieser et al., 2010). Similarly, high but not low social anxiety in women was linked with greater heart rate acceleration in response to direct, as compared to averted gaze (Wieser et al., 2009). Highly socially anxious individuals demonstrated avoidance of angry facial expressions but only when gaze was direct (vs. averted); however, they exhibited avoidance of smiling expressions regardless of gaze direction (Roelofs et al., 2010). Furthermore, an fMRI study confirmed preferential activation of brain areas related to fear response when SAD patients viewed direct gaze vs. averted gaze (Schneier et al., 2009).

It appears that sensitivity to EFEs may be modulated by gaze direction. Overall, direct (rather than averted) gaze results in higher physiological and neurological responsiveness as well as more pronounced avoidance among individuals high on social anxiety than those low in social anxiety. This sensitivity appears to be accentuated by emotional expressions; yet, more studies are needed to understand the nature of expression-gaze interaction. For example, depending on the emotional expression, direct gaze may suggest aggressive/dominant intent (when paired with angry

or even neutral facial expressions) or affiliative intent (when paired with smiling).

To summarize, the EFE literature suggests that in no-stress conditions social anxiety is associated with generalized reactivity to emotional and neutral faces alike. In addition, in some but not all tasks, social anxiety is associated with selective processing of threatening EFEs, and this bias appears to be modulated by the direction of the targets' gaze. Moreover, smiling facial expressions sometimes elicit reactions similar to those elicited by threatening EFEs. The latter finding highlights the complexity of examining facial expressions because they might simultaneously connote dominance and affiliation (Knutson, 1996). Thus, smiles could be negatively interpreted as threatening by virtue of their association with dominance. Alternatively, affiliative signals may invoke expectations of reciprocity, triggering self-evaluative concerns, which in turn can lead to fear and avoidance. The literature may benefit from better understanding how EFE processing is affected by contextual variations (such as gaze, head tilt, or gender) as well as by the perceiver's motivational states.

VOICE

Vocal information is an important channel for assessing an interaction partner's emotional states, intentions, and trait predispositions (Scherer, 1981; Siegman, 1987). Voices are processed early (e.g., Sauter and Eimer, 2010) and automatically (Donohue et al., 2012). Given the importance of vocal communication to the interpretation of social messages, it is surprising that only a handful of studies examined biased processing of vocal information in social anxiety. Existing studies involving social anxiety focus on labeling of, and brain responses to, emotional prosody of various utterances.

In the first study of its kind, Quadflieg et al. (2007) asked individuals with SAD and control participants to label the emotions of pseudo-words pronounced in angry, sad, happy, fearful, disgusted, or neutral tones by male and female actors. Compared to controls, individuals with SAD were more likely to label utterances as fearful or sad. Importantly, like in the evaluation of facial expressions, no group differences emerged regarding valence and arousal ratings for any of the emotional utterances.

In a follow-up study, individuals with SAD and matched controls labeled the emotion or gender of words pronounced with angry or neutral prosody by male and female actors during fMRI scanning (Quadflieg et al., 2008). Angry prosody elicited stronger brain activation than neutral prosody in limbic (insula, amygdala) as well as cortical areas for all participants. Importantly, compared to controls, individuals with SAD had increased activation in the right orbitofrontal cortex in response to angry vs. neutral voices under both task conditions. These results again substantiate findings for EFEs. McClure and Nowicki (2001) examined interpretation of EFE and vocal prosody in children who were high or low on social anxiety. Social anxiety was significantly associated with greater confusion in emotional labeling of vocal cues, where the high anxiety group was more likely than their less anxious peers to confuse other children's sad and fearful voices.

Taken together, the study of vocal prosody suggests that social anxiety appears to affect the interpretation of prosody characteristics. However, to the best of our knowledge, no studies to date examined attention to, or memory for, prosodic information. Moreover, biases in interpreting affectionate prosody remain to be explored.

BODY AND POSTURE

In the last decade, research on facial and vocal displays of emotions has been augmented by the study of postural expressions (e.g., Tracy and Robins, 2004; App et al., 2011; Dael et al., 2012). Indeed, posture appears particularly important for portraying and recognizing affective states. Posture and associated body language serve as a rich source of information for revealing others' goals, intentions, and emotions. These signals are visible and interpretable from a distance, do not require close contact, and allow simultaneous transmission of information to multiple individuals (e.g., Reed et al., 2003, 2006). The ability to engage in configural body processing seems to develop as early as 3 months of age (Gliga and Dehaene-Lambertz, 2005). Fearful, angry, and happy postures can be processed without visual awareness (Stienen and de Gelder, 2011). In addition, postures also transmit signals pertaining to individuals' social rank or status (e.g., Shariff and Tracy, 2009). For example, pride is cross-culturally recognized and easily distinguished from other similar emotions (e.g., happiness; Tracy and Robins, 2007). Recently, Rule et al. (2012) found that perceivers' judgments of posture dominance were significantly more accurate than chance guessing for exposures as brief as 40 ms, with no significant increase in accuracy given additional viewing time.

Few studies have examined processing of postural or any bodily information in social anxiety. Pitterman and Nowicki (2004) found that adults' correct labeling of standing postures (depicting happiness, fear, anger, and sadness) correlated negatively with fear of negative evaluation. In addition, compared to children with attention disorders, children high in social anxiety made more errors identifying angry posture in adult posers (Walker et al., 2011). De Gelder and her colleagues examined how negative affectivity and social inhibition associate with the processing of threatening body expressions (fear and anger; Kret et al., 2011). They found that negative affectivity correlated with deactivation of the core emotion system (e.g., amygdala, right insula), whereas social inhibition correlated with a tendency to activate a broad cortical network (e.g., orbitofrontal cortex). Although tentative, these results suggest that social anxiety may be associated with enhanced processing of threatening or dominant postures.

STABLE FEATURES OF FACES, VOICES, AND BODIES

Another line of research explores the perception of stable characteristics (such as facial symmetry, vocal characteristics, and body size) as indicative of various psychological features (Tinlin et al., 2013). Substantial evidence indicates that people instantly form impressions from facial characteristics (e.g., Bar et al., 2006) and that these impressions affect important decisions (e.g., Olivola and Todorov, 2010). Regarding faces, individuals' facial maturity was linked to their perception as dominant. When baby-faced targets were paired with submissive information (congruent condition), they were better remembered than when they were paired

with dominant (non-congruent) information (Cassidy et al., 2012). In addition, increase in men's face-width-to-height ratio was linked to their faces being perceived as more aggressive (Carré et al., 2010). Thus, stable facial characteristics appear influential in judgments of people as dominant and/or affiliative.

Studies with non-clinical populations have examined the influence of stable auditory characteristics of voice—especially pitch—on trait judgments. Specifically, male participants made judgments of likely physical aggressiveness based on vocal recordings of men reading a sentence, which were raised or lowered in both fundamental frequency (F0) and formant dispersion (df; Wolff and Puts, 2010). Raised vocal masculinity (lowered F0 or df) yielded higher dominance ratings. Moreover, raters with either high or low levels of testosterone rated other men as more dominant than raters with mean levels of testosterone.

Stable characteristics of body may also influence perceptions of power and dominance. Height is an important factor, as taller individuals were perceived as more dominant (Adams, 1980; Melamed, 1992; Young and French, 1998), even when females were evaluated (Boyson and Butler, 1999).

Recent studies from our group have shown that social anxiety is associated with biased impression formation and impression revision from trait descriptions (Aderka et al., 2013; Haker et al., 2013). Yet, to date, studies have yet to assess the role of social anxiety in the interpretation of static characteristics of the faces, voices, or bodies. Such an endeavor may enrich understanding of how social anxiety affects person perception.

INTEGRATED NONVERBAL REPRESENTATIONS

Integrating information from face, voice, and body plays a crucial role in human ability to understand social interactions. Although distinct, these different sources of information are normally processed in parallel, and, when synchronous, facilitate social comprehension. In contrast, the study of channel incongruity may enable understanding of the relative diagnostic value of each component of person perception. For example, participants predicted that the face would be most influential on perceptions of winning and losing emotions; however, the body was the best diagnostic feature (Aviezer et al., 2012). Rule et al. (2012) also found that face-body gestalt increased accuracy in perceiving dominance expressions from bodies and faces. Van den Stock et al. (2007) demonstrated that body postures conveying emotions influenced recognition of facial expressions and tones of voice. These findings emphasize the importance of emotional whole-body expressions, as well as the combination of NVSCs in everyday settings. With respect to social anxiety, the examination of conflicting cues—such as those connoting threat in one channel and affiliativeness in another—may elucidate the relative diagnosticity of each information type for socially anxious individuals.

EVALUATIVE SUMMARY OF NONVERBAL SOCIAL CUE (NVSC) PERCEPTION

Taken together, the research reviewed above suggests that individuals with high social anxiety are more likely than peers with low social anxiety to misinterpret EFEs and vocal expressions of emotions, although results pinpointing threatening misinterpretations were not as robust as theoretically expected. While pertinent studies on body posture are scarce, it appears likely that socially anxious individuals may be also biased in processing these stimuli. Examination of socially anxious individuals' perceptions of nonverbal representations of social status cues is important, given that social status is central to evolutionary (e.g., Gilbert and Trower, 2001), interpersonal (Alden and Taylor, 2004), and cognitive (e.g., Clark and Wells, 1995) accounts of social anxiety.

PRODUCTION OF NONVERBAL SOCIAL CUES (NVSCs)

Existing research has focused on NVSC perception, but multiple considerations indicate the need to extend investigation to the domain of NVSC production. First, examination of expressive indices of emotion can substantially complement subjective reports by linking research on adult humans to research on infants (Cappella, 1981) and non-human primates (e.g., Geerts and Brüne, 2009). Second, expressivity was pinpointed as an important clue for judging cooperation (e.g., Boone and Buck, 2003; Schug et al., 2010) and thus may direct an interaction's outcome. Third, based on embodied cognition accounts, researchers found that expressive behaviors lead to cognitive change (Briñol et al., 2011). These behavior-cognition and cognition-behavior links may generate either a self-enforcing positive or negative cycle, again influencing the course of interactions. Finally, NVSC production was shown to predict the long-term course of depression following treatment (Bos et al., 2006, 2007). Thus, NVSC production may possibly also be used to predict treatment outcomes in social anxiety.

FACES

Facial mimicry

Mimicry has been conceptualized as affiliative social behavior where one emulates another person's nonverbal actions (Lakin and Chartrand, 2003). By and large, mimicry was found to generate positive social feelings (Chartrand and Bargh, 1999). For example, priming individuals with prosocial (as opposed to antagonistic) goals generated more mimicking behavior (Leighton et al., 2010). Also, a priori manipulation of liking for another increased mimicry (Stel et al., 2010). Furthermore, automatic mimicry responses increased following a social exclusion situation, possibly because the threat of exclusion promoted affiliative motivations and actions (Lakin et al., 2008).

Importantly, mimicry depends on an interaction's nature; competitive interactions seem to elicit less facial mimicry than collaborative interactions (Likowski et al., 2011). Lower mimicry in competitive situations may be conceptualized as complementary behavior, where dominant displays (e.g., anger) elicit submissive reactions (e.g., fear). Interestingly, mimicry not only affects this social signal's recipient but also it's expresser: women were slower to recognize the affective valence of briefly displayed facial expressions when constrained from mimicking them (Stel and van Knippenberg, 2008). This effect was attributed to the fact that facial constraints hinder women's capacity to empathize.

Only a handful of studies explored automatic facial mimicry in social anxiety. In the first study to address this issue, Dimberg (1997) found that women high in public speaking fearfulness reacted with more frowning to angry faces than did women low in public speaking fearfulness, and women low in public speaking

fearfulness exhibited more reactivity to happy facial expression than did women high in public speaking fearfulness (Dimberg, 1997). Vrana and Gross (2004) found that individuals high in public speaking fear exhibited more frowning in response to angry, neutral and happy facial expressions than did individuals low in speech fearfulness. Finally, Dimberg and Thunberg (2007) found that the individuals in a high public speaking fear group exhibited greater negative facial reactivity when responding to angry vs. happy faces, and greater positive emotional reactivity when responding to happy, as compared to angry faces. Given the recent emphasis on importance of mimicry for the establishment of rapport and liking on the one hand, and the deficits in affiliative behavior in social anxiety on the other (e.g., Alden and Taylor, 2011), more studies examining mimicry in social anxiety are needed.

Facial expressivity: voluntary displays of affect

Emotional expressivity is the extent to which an individual manifests emotional impulses behaviorally (Gross and John, 1997). Emotional expressivity was linked to increased positive affect (Gross and John, 1995; Burgin et al., 2012), whereas suppressing emotional displays was shown to decrease positive affect (Gross, 1998). Emotional expressivity was also linked to better social functioning (Burgin et al., 2012), cooperativeness (Schug et al., 2010), and agreeableness (Gross and John, 1995). Moreover, expressivity is beneficial not only when it concerns positive emotions. Feinberg et al. (2012) found that people who expressed embarrassment were judged as more prosocial. In terms of dominance, Hall et al. (2005) found that more gazing, nodding, and smiling and a generally more expressive face were associated with high interpersonal power.

Social anxiety is linked to lower levels of emotional expressivity (Kashdan and Breen, 2008), and is found to be mediated by beliefs that overt emotional expression is negative (Spokas et al., 2009). Moreover, Kashdan et al. (2011) found that the negative correlation between social anxiety and positive affect was mediated by the tendency to suppress emotional displays.

In sum, expressivity emerges as an important nonverbal variable in social interactions, signaling both dominant and affiliative propensities. Social anxiety is associated with lower levels of expressivity, constituting a potential deficiency in both social domains.

Eye gaze

Robust evidence suggests that avoidance of eye contact may be a central characteristic of SAD (e.g., Schneier et al., 2011). Specifically, fear and avoidance of eye contact consistently correlate with overall severity of social anxiety (e.g., Safren et al., 1999; Baker and Edelmann, 2002; Stein et al., 2004), and were recently found to decrease with successful treatment (e.g., Schneier et al., 2011). Studies relying on independent observers' judgments revealed that individuals with SAD made less eye contact during social interactions than individuals low in social anxiety (Baker and Edelmann, 2002; Voncken and Bögels, 2008). Advancements in eye-tracking methodology have permitted in-depth examination of this feature of socially anxious behavior: Individuals with SAD showed fewer gaze fixations on the eyes when facial expressions were presented for relatively long time intervals (e.g., Horley et al., 2004; Moukheiber et al., 2010, 2012; but see also Wieser et al., 2009).

Theoretically, gaze avoidance has been linked to submissive behavior in a variety of species (e.g., Mazur and Booth, 1998). Inasmuch as human social anxiety has been postulated as related to such submissive behaviors (e.g., Gilbert, 2001), perhaps gaze processing in social anxiety holds promise for creating a neurobiological marker of this disorder.

VOICE

Individuals with SAD are often concerned about showing auditory signs of anxiety during social performance (e.g., Hirsch and Clark, 2007). Early studies seeking to examine the veracity of these concerns tested the vocal performance of socially anxious individuals in interpersonal situations. Such highly socially anxious individuals were often rated by others as less competent in their vocal communication compared to controls (e.g., Borkovec et al., 1974; Fydrich et al., 1998; see review in Baker and Edelmann, 2002). Further studies highlighted relations between social anxiety and temporal features of spontaneous speech. For example, highly socially anxious and clinically distressed individuals with SAD paused more often and for longer durations, demonstrated slower speech rate, and evidenced restricted verbal output (e.g., Borkovec et al., 1973; Lewin et al., 1996; Hofmann et al., 1997).

In a pioneering study, Laukka et al. (2008) used acoustic analysis to explore the effect of social anxiety on objectively defined auditory parameters. Public speech samples of individuals with SAD were recorded preceding and following pharmacological intervention. Participants who reported lower anxiety following treatment demonstrated post-treatment decreases in mean F0 (subjectively perceived as pitch) and decreased proportions of silent pauses. In another study, Weeks et al. (2011) placed socially anxious men in a competitive interaction with another man over the positive attention of a female peer. Consistent with evolutionary predictions, highly socially anxious men manifested increased mean F0, whereas men low in social anxiety showed the opposite trend. Recently, Weeks et al. (2012) also compared acoustic characteristics of public speaking between a group with SAD and non-anxious controls. Males with SAD evidenced greater F0 in comparison to non-anxious individuals across both studies. For females, the inverse correlation between social anxiety and F0 was significant only when examined in patients with generalized SAD, and in response to in vivo social exposures. Importantly, gender-specific thresholds for mean F0 demonstrated excellent differentiation between patients with generalized SAD and non-anxious controls.

Galili et al. (2013) examined college students' vocal characteristics as a function of social anxiety by asking participants to record neutral, command, and request sentences and then analyzing these utterances' acoustic properties (mF0, intensity, speech rate, speech fluency). Social anxiety was associated with higher mF0 in men and women and with lesser vocal intensity in men. Moreover, compared to neutral sentences, social anxiety was associated with lesser increase of vocal intensity in command utterances, and with greater decrease of vocal intensity in request utterances. In men but not women, social anxiety also correlated

with slower speech rate in request sentences. Taken together, these results pinpoint F0 as a promising biobehavioral marker of social anxiety (at least in men). Moreover, vocal intensity, speech rate, and speech fluency also seem likely to be affected by social anxiety in socially stressful situations.

Other nonverbal parameters of speech such as volubility (time spent talking; Mast, 2002; Brescoll, 2012), successful interruptions (Farley, 2008), vocal expressivity (e.g., Dunbar and Abra, 2010), initiation of speech acts, and laughter (Gifford and Hine, 1994) have been linked with high interpersonal power. Likewise, volubility was the best predictor of observer-rated social performance in an interaction task (Stevens et al., 2010). Similar findings emerged in an impromptu speech task, where socially phobic patients exhibited significantly less volubility than individuals low in social anxiety (Beidel et al., 2010).

In sum, different aspects of acoustic performance appear to link significantly with social anxiety. Acoustic parameters of speech associate closely with manifestations of power and social rank in both humans (e.g., Dunbar and Abra, 2010) and other mammals (e.g., Koren et al., 2008; Laporte and Zuberbühler, 2010). Altogether, these findings point to the possible diagnosticity of this expressive behavior.

POSTURE AND BODY MOVEMENT

Body posture and movement are important indicators of powerful behavior. Specifically, power is associated with more bodily openness, more erect or tense posture, and more body or leg shifts (Hall et al., 2005). Recently, Weeks et al. (2011) found that high social anxiety levels were associated with slumped and closed posture when interacting with a male competitor, whereas low social anxiety was associated with expansive posture. Other studies on observer ratings found that socially phobic individuals exhibited more bodily discomfort during social or performance tasks, such as rigidness and fidgeting (Voncken and Bögels, 2008; Heiser et al., 2009). Finally, measurement of observers' head movements showed that, when viewing an avatar's whole body, observers with high social anxiety mimicked the avatar significantly less than individuals with low social anxiety (Vrijsen et al., 2010).

EVALUATIVE SUMMARY OF NONVERBAL SOCIAL CUE (NVSC) PRODUCTION

Vocal and bodily behaviors appear linked to social anxiety and to expression of social rank. Facial expression and eye gaze seem linked both to expression of dominance (e.g., anger, contempt) and expression of affiliation (e.g., smiles). Existing research indicates that highly socially anxious individuals, especially males, will more likely exhibit submissive behaviors than individuals with low social anxiety.

Production of non-affiliative or submissive NVSCs is likely to deepen people's sense of disconnection and/or ineptitude either by directly influencing cognitions (e.g., Briñol et al., 2011) or through standards of culturally-appropriate behavioral norms (e.g., one should look one's offender in the eye, rather than lowering one's head; people should look others in the eye and smile). Thus, gaining more complete, complex understanding of NVSC production may advance more nuanced conceptualizations of interpersonal and situational factors that influence self-evaluations in social anxiety.

INTEGRATION OF THEORETICAL APPROACHES TO SOCIAL ANXIETY

NONVERBAL SOCIAL CUES (NVSCs) AT THE EPICENTER OF SOCIAL ENCOUNTERS

Independent theoretical contingents have identified different factors contributing to the maintenance of social anxiety: cognitions (e.g., Clark and Wells, 1995; Rapee and Heimberg, 1997; Gilbert, 2001; Hofmann et al., 2004), interpersonal factors (e.g., Alden and Taylor, 2004), or evolutionary pressures (Gilbert, 2001). Recent attempts were made to integrate these theoretical literatures. Our lab proposed a cognitive-evolutionary model (e.g., Aderka et al., 2013; Galili et al., 2013; Haker et al., 2013; Gilboa-Schechtman et al., in press), and several other researchers (Levinson et al., 2011; Taylor and Alden, 2011; Moscovitch et al., 2012) argued for a cognitive-interpersonal hypothesis. To varying degrees, the cognitive, interpersonal, and evolutionary models implicate abnormal social behavior and cognition in the onset and maintenance of social anxiety. Indeed, the three theories tend to be more complementary than contradictory. Importantly, all three postulate that socially anxious individuals are biased when perceiving social signals such as facial expressions, and because those signals guide interpersonal interactions, that bias leads to important outcomes. Interpersonal theories, evolutionary theories, and cognitive embodiment accounts also highlight the importance of the production of interpersonal signals (e.g., smiles, powerful postures) for the coordination of social interactions. Thus, the processing and production of NVSC is the juncture at which these theories intersect.

The evolutionary/interpersonal dimension of social rank and affiliation refine and sharpen the cognitive categories of threat and safety. Consider, for example, a case of an expanded pride posture (Tracy and Robins, 2004). While such posture may not represent social threat, it does connote an attempt to ascend in social rank. According to our account, such cues are likely to be selectively processed by individuals high in social anxiety. Conversely, the cognitive-embodiment account help explain the link between intra- and inter-personal mechanisms. For example, an assertive voice tone engenders a sense of self-assurance, which, in turn, elicits a complimentary (e.g., obliging, submissive) response from the interaction partner (e.g., Tiedens and Fragale, 2003). Moreover, we claim that the maintaining factors in social anxiety rely not only on the way individuals' process NVSC (the self-as-receiver of information) but also on the way individuals' *express* socially relevant attitudes and behavior (the self-as-an-agent).

REACTIVITY TO SOCIAL STRESS IN SOCIAL ANXIETY: NONVERBAL SOCIAL CUE (NVSC) AND BEYOND

Most theoretical models of SAD consider heightened sensitivity to, enhanced responsivity to, and impaired regulation in the face of social threat to be at the epicenter of this condition (e.g., Clark and Wells, 1995; Rapee and Heimberg, 1997; Gilbert and Trower, 2001; Hofmann et al., 2004). Individuals with SAD reported heightened emotional reactions to both positive and negative social events (e.g., Gilboa-Schechtman et al., 2000). Experimental

interpersonal manipulation studies consistently found that individuals with high social anxiety or SAD reported more intense, persistent negative affect in anticipation of, and following, various social challenges such as public speaking (e.g., Rapee and Lim, 1992; Ly and Roelofs, 2009), social ostracism (Oaten et al., 2008) and social success (Wallace and Alden, 1997) compared to individuals with low social anxiety.

Research has yet to examine the impact of social anxiety on the sensitivity to and bias in interpreting NVSCs following social stress. As our review suggests, two types of distinct social events appear crucial for such future examination: events indicating changes in belongingness (e.g., social exclusion, gaining social favor) and events indicating changes in social rank (e.g., defeat, victory). Examination of sensitivity to diverse stressors is pivotal, as sensitivity to interpersonal cues signaling affiliation or social rank is essential for smooth navigation in the interpersonal world, especially when one seeks to recover from a social misfortune or to capitalize on social success. For example, following exclusion, a failure to correctly identify potential friends or allies (vs. foes) is likely to hamper social reintegration, thereby increasing the threat of additional rejection. Similarly, the failure to assert oneself once a social group observes one's positive qualities or deeds may hamper one's chances of advancing in the social hierarchy. Finally, the mediating effects of social anxiety on the tendency to interpret NVSCs as affiliative or dominant may elucidate the causal structure of attunement difficulties in this population.

FUTURE DIRECTIONS

The present perspective calls for several directions of future research. First, the current unified perspective accentuates the need to study gender differences in perceiving and perhaps even more so in expressing NVSCs. Men and women face somewhat different threats in navigating groups; women face greater risk for exclusion, whereas men face greater risk for physical defeat (e.g., Archer, 2004; Benenson et al., 2011). Thus, we can expect gender to moderate the relations between social anxiety and perception of exclusion and dominance signals, where women are more sensitive to exclusion and men to dominance. Moreover, based on the tend-and-befriend theory of women's response to social threat, females may be expected to engage in more affiliative gestures following exclusion or defeat, whereas men may be more likely to express signals of deference or submissiveness (Taylor, 2006).

Second, existing evidence points to the possibility that embodiment of powerful NVSCs may lead to congruent changes in cognitions and cognitive processing and, conversely, the adoption of submissive NVSCs may deepen existing cognitive biases. For example, recent studies by Galinsky et al. (2006) suggested that merely thinking about powerful experiences enhances performance (Lammers et al., 2013). Moreover, both power postures and power roles were shown to reduce interpersonal fearfulness and increase approach behaviors; yet, power postures were more effective (Huang and Galinsky, 2010). Similarly, recent studies found that pitch does not merely correlate with social rank—it also instills subjective feelings of dominance and cognitive correlates of power (Stel et al., 2012). Altogether, these studies suggest reciprocal patterns of influence between NVSCs and cognition, with dominant expressions enhancing sense of power and submissive expressions decreasing it. Thus, loss of felt power may result in fewer displays of expressive behaviors in general and greater displays of submissive or appeasement behaviors (Stel et al., 2012). Such changes in expressive production may foster self-perceptions of powerlessness. These findings underscore an intriguing possibility for embodiment-focused cognitive interventions, such that socially anxious individuals may engage in training to implicitly or explicitly affect their sense of power or dominance.

Finally, research on NVSCs may provide converging evidence regarding the brain circuits engaged in social anxiety. For example, if processing of several types of NVSCs is found to involve overlapping circuitry (amygdala, insula, DLPFC), such brain areas may be associated with a special significance for social anxiety. More broadly, focusing on the social rank and affiliation systems may offer a new and helpful conceptual framework to examine brain mechanisms previously labeled approach-related and avoidance-related (e.g., Quirin et al., 2013; Terburg and van Honk, 2013).

CONCLUSION

NVSC are signals with long evolutionary history. As such they figured prominently in cognitive, interpersonal, and evolutionary accounts. In the present review we emphasized the links between biased processing of NVSC and social anxiety, highlighting the tendency of the socially anxious to be sensitive to social status cues. We also emphasized that production of non-affiliative or submissive NVSCs is likely to deepen a sense of disconnection and ineptitude. Given these propensities, socially anxious individuals might perceive and remember the social world as a hierarchical and competitive arena. These perceptions, in turn, may lead to a persistent sense of incompetence and inferiority (Gilbert et al., 2009). In the review we emphasized the interplay between perception and expression of NVSC as concomitant with social anxiety; future work would profit from examining the causal status of NVSC as contributing to the onset and maintenance of this condition.

EXPERT REVIEW

Psychobiological risk factors for suicidal thoughts and behaviors in adolescence: a consideration of the role of puberty

Abstract

Suicide is the second leading cause of death among adolescents. While clinicians and researchers have begun to recognize the importance of considering multidimensional factors in understanding risk for suicidal thoughts and behaviors (STBs) during this developmental period, the role of puberty has been largely ignored. In this review, we contend that the hormonal events that occur during puberty have significant effects on the organization and development of brain systems implicated in the regulation of social stressors, including amygdala, hippocampus, striatum, medial prefrontal cortex, orbitofrontal cortex, and anterior cingulate cortex. Guided by previous experimental work in adults, we also propose that the influence of pubertal hormones and social stressors on neural systems related to risk for STBs is especially critical to consider in adolescents with a neurobiological sensitivity to hormonal changes. Furthermore, facets of the pubertal transition, such as pubertal timing, warrant deeper investigation and may help us gain a more comprehensive understanding of sex differences in the neurobiological and psychosocial mechanisms underlying adolescent STBs. Ultimately, advancing our understanding of the pubertal processes that contribute to suicide risk will improve early detection and facilitate the development of more effective, sex-specific, psychiatric interventions for adolescents.

Introduction

Suicide is the second leading cause of death among adolescents ages 10–24 years worldwide [1] and accounts for 17.7% of all deaths in youth ages 15–24 years in the United States [2]. Although suicide has a relatively low prevalence, over the past 10 years suicide rates in the US have increased by 76% in youth ages 15–19 years and, more alarmingly, by 300% in youth ages 10–14 years [3]. Despite the urgency of suicide as a public health problem, research examining predictors of suicidal thoughts and behaviors (STBs) has had limited clinical impact, particularly in adolescents [4, 5]. Adolescents report a higher proportion of suicidal ideation and attempts than do adults, making this a critical developmental period during which to identify early risk factors for STBs [6]. Indeed, the fact that adolescent samples represent only 20% of the literature on predictors of STBs further underscores the need for more research with this age group [5].

While clinicians and researchers recognize that predictors of STBs are multidimensional—including genetic, epigenetic, neurobiological, psychosocial, and environmental factors—the marked increase in the prevalence of STBs (and mental health conditions more generally) during adolescence [7] suggests that this developmental period, in which the confluence of these multidimensional influences contributes to elevated risk, is unique [8, 9]. In this context, we contend that one critical factor is puberty. The onset of puberty initiates a neuroendocrine cascade that shapes the maturation of neural circuits that underlie a range of socioemotional and cognitive functioning, including emotion regulation and impulse control. Impaired emotion regulation and impulse control both significantly contribute to the emergence of mental disorders in the face of environmental risk factors (e.g., life stress) that influence neurodevelopmental trajectories, result in the generation and experience of additional psychosocial stress, and, thus, may represent an important pathway to developing

STBs. Other notable aspects of development, such as pubertal timing, and factors that may drive atypical pubertal timing (e.g., exposure to early adversity), are also recognized as important in affecting the development of adolescent-onset psychiatric disorders, including STBs [10]. Indeed, atypical pubertal timing results not only in corresponding changes in neuroendocrine systems but also significant shifts in social identity and perceived status may explain sex differences in the emergence and course of STBs (and related mental health conditions that substantially increase the risk of STBs).

The goal of this review paper is to elucidate how pubertal changes contribute to STBs in adolescence. While we do not regard puberty-related processes as primary determinants of STBs, we posit that exposure to sex hormones during adolescence initiates a period of plasticity in neural circuits that are sensitive to social context (including social stressors that amplify emotion dysregulation and impulse control in ways that increase risk for STBs) and that may be target mechanisms for treatment of STBs, We further contend that these processes are especially critical to consider in adolescents who have existing vulnerabilities, including neurobiological sensitivity to hormonal changes, exposure to adverse psychosocial experiences during early development, and underlying mental disorders. In the following sections, we: (1) present an overarching framework and highlight specific brain circuits involved in social cognition, emotion regulation, and impulse control that are relevant to understanding STBs in adolescence; (2) review basic experimental findings in adults that show the effect of pubertal hormones on behaviors relevant to suicide risk and survey the conflicting correlational literature on hormones with STBs in adolescents; (3) discuss the role of pubertal timing and sex differences in these processes; and (4) advance recommendations for future research in this area.

Puberty as a driver of neuroendocrine mechanisms relevant for understanding adolescent STBs

Contemporary theories of suicide have been informed primarily by data from adults [11, 12], it is unclear whether these theories—or specific components of associated models—extend to adolescents. Moreover, few theories of suicidality explicitly integrate biological factors, including endocrine or neural factors (with exceptions [12–14]). Here, we posit that adolescent STBs result from a pathological response to stress during a time when the neurobiological systems that regulate stress are recalibrating. There is extensive evidence that STBs in adolescents are often preceded by life stressors, particularly stressors characterized by interpersonal rejection, loss, or conflict [15–17]. Social rejection in particular is a commonly experienced stressor during adolescence due to unstable romantic and peer relationships, and is a potent trigger for negative emotions [18, 19]. In this context, emotion-related impulsivity—the tendency to react impulsively during experiences of heighted affective states [20]—may contribute to adolescent risk for STBs. Indeed, both peer-related stressors [21, 22] and emotion-related impulsivity [23] have been shown separately to predict STBs in adolescents.

We argue here that hormonal changes during puberty alter the development of brain circuits implicated in the regulation of social stressors. The brain is a target organ for all of the pubertal hormones we review, and receptors for these hormones are expressed abundantly in several key structures that comprise brain networks governing social cognition, emotion regulation, and impulse control generally (and social rejection and emotion-related impulsivity specifically) [24, 25], including the amygdala, hippocampus, striatum, anterior cingulate cortex (ACC), medial prefrontal cortex (mPFC), and orbitofrontal cortex (OFC). The amygdala, hippocampus, and ACC comprise a network of regions implicated in detecting social salience; the amygdala and mPFC comprise a key emotion regulatory circuit; the striatum and frontal regions including OFC comprise circuits underlying reward valuation and impulse control. It is important to note that many of these regions already exhibit sexual dimorphism during adolescence, including larger amygdala and hippocampal volumes in boys, greater variance in the hippocampus and striatum in boys than in girls, sex differences in white matter organization of callosal, cerebellar, and long-range association tracts (for a review, see [26]), and sex differences in the developmental trajectories of frontoparietal networks [27]. Moreover, several of these regions have been highlighted in a recent review of neuroimaging markers associated with STBs across the lifespan [28]; however, those authors did not consider the importance of pubertal development in explaining the neuroendocrine basis of the emergence of STBs. We contend that this is a critical factor to consider, given emerging evidence that sex differences in these brain circuits during adolescence appear to be explained, at least in part, by changes in pubertal hormones [29, 30]. Thus, we contend that the social landscape, and most notably environmental stressors, experienced by boys and girls begins to differ during puberty, and that these differences, in conjunction with sex-specific hormonal effects on brain maturation, may explain important sex differences in STBs that emerge by mid-adolescence.

Pubertal hormones and suicide-relevant thoughts and behaviors

Puberty is composed of two phases: *adrenarche* and *gonadarche*. During adrenarche, which typically begins around ages 7–8 years, the adrenal glands produce increasing levels

of the hormones dehydroepiandrosterone (DHEA) and testosterone [31, 32]. Gonadarche is a longer process that typically takes 4–5 years, beginning around ages 9–10 and occurring on average a year earlier in girls than in boys [33]. Gonadarche is triggered by the activation of hypothalamic-pituitary-gonadal (HPG) axis, which leads to rising levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The release of LH and FSH initiates the development of the gonads, which, in turn, leads to increases in sex hormones—specifically, testosterone in boys and estradiol (the predominant estrogen during adolescence) and progesterone in girls—and, by early to mid-adolescence, the development of secondary sex characteristics and other physical changes [32]. Importantly, these hormones cross the blood brain barrier, influence brain development, and affect a wide variety of signaling pathways (e.g., neurotransmitter activity) that underlie mood and cognition [25]. Thus, puberty involves transformation across virtually every psychobiological domain—endocrine, neural, physical, cognitive, and socioemotional—and represents a vulnerable time during which STBs may emerge.

Prevalence rates of STBs begin to increase after age 12 but peak in later adolescence, suggesting that it is not simply the rise in these hormones that accounts for the increase in STBs, given that these endocrine changes begin much earlier than age 12. Instead, the organizational effects of pubertal hormones play a major role in risk for STBs in adolescence. Organizational effects are those that occur during sensitive periods of development that lay the foundation for sex-typical brain and behavioral phenotypes and, thus, have an impact even in the absence of circulating levels of the hormones. In contrast, activational effects facilitate the expression of behaviors under specific contexts but are temporary and occur only when the hormones in question are present [34]. Evidence for organizational effects of hormones during adolescence comes from studies demonstrating that the same developmental processes (e.g., neurogenesis, synaptic pruning, dendritic branching, apoptosis) that occur during the perinatal period as a result of surging levels of gonadal hormones also occur during puberty [35, 36]. These studies suggest that puberty opens a sensitive window for experience-dependent plasticity in neural circuits that underlie higher-order processing of social stimuli, thereby rendering adolescence—a time of increased exposure to social stressors—a vulnerable period for the onset of stress-related mental health problems (Fig. 1). At the same time, it is possible that ongoing fluctuations in hormone levels are also related to STB risk through their activational effects on neurotransmitter systems, particularly in the context of responding to social stressors, and that these effects are more relevant for adolescents with a neurobiological sensitivity to hormonal changes.

Below, we review studies investigating ovarian (estradiol and progesterone), testicular (testosterone), and adrenal (DHEA) hormones in relation to STBs and, importantly, their impact on the structural development and function of specific brain circuits implicated in social cognition, emotion regulation, and impulse control. A summary of this section is outlined in Table 1 and Fig. 1B. Before reviewing the correlational literature in adolescents, within each respective section, we first review basic experimental studies that provide insight concerning the effects of estradiol, progesterone, testosterone, and DHEA on human behaviors relevant to suicide risk in adults in order to provide a more reliable context for the actions of these hormones.

Finally, because ovarian hormones have been investigated almost exclusively in females in this context and, similarly, androgen hormones overwhelmingly in males, our review of the association of these hormones with brain and behavioral outcomes inherently raises issues of sex differences or sex-specific effects in these processes; we discuss these issues in more detail in a later section (D. Consideration of sex differences).

Ovarian hormones (estradiol and progesterone)

Estradiol, progesterone, and their neurosteroid metabolites all increase and begin to fluctuate cyclically in girls during puberty [34]. Consequently, the vast majority of research in this area has focused on females (for reviews, see [14, 37]). To provide a context for understanding the effects of estradiol and progesterone administration on behaviors relevant to suicide risk, we will first briefly review studies that controlled hormone conditions in women with affective symptoms and premenstrual dysphoric disorder (PMDD), for whom suicide risk is elevated compared to the general population [38, 39].

Decades of research have shown that there are no differences between women with and without PMDD in ovarian hormone levels or related neurosteroids (e.g., allopregnanolone) but that suppressing ovarian hormones reduces or eliminates symptoms of PMDD (for a review, see [40]). A recent study that controlled for ovarian hormone secretion and exposure in women with PMDD has helped to clarify these two seemingly opposing findings [41]. In that study, women with PMDD who responded to a gonadotropin-releasing hormone agonist treatment were given placebo for one month before being administered continuous estradiol/progesterone for three months; researchers found that changes from low to high levels of ovarian hormones, but not absolute levels of ovarian hormones, were associated with increases in negative affect [41]. Together, these data suggest that neurobiological sensitivity to hormone *changes* is an important factor that may explain certain clinical phenomena, such as PMDD and suicide risk. Indeed, a recent review has covered this topic extensively in adult women, demonstrating that cyclical

hormone changes may play an important role in "acute risk for daily suicidal ideation, planning, and intent" in individuals with sensitivity to hormone changes [14]. We have extended this theoretical model to adolescents, proposing that in those who possess a neurobiological sensitivity to hormonal changes, the normative fluctuations during this transitional period, coupled with adolescent-typical experiences of greater exposure to life stressors, may exacerbate the effects of these processes on emotion regulatory and impulse control circuits. Indeed, results from studies that have investigated suicide risk in adult women across the menstrual cycle have been inconsistent. These studies have typically assessed levels of estradiol and progesterone during different phases of the menstrual cycle [42–44], and in women with low levels of estradiol and progesterone (e.g., amenorrhea or menopause [45]). While some investigators have reported that a higher risk of suicide attempts and more severe suicidal thoughts and intentions are associated with relatively low or declining levels of estradiol and progesterone (i.e., during the early follicular/menstrual or pre-menstrual phases), other researchers have not found differences in estradiol or progesterone between depressed women with and without STBs [46] or effects of the menstrual cycle on suicide attempts in women with PMDD [39].

The fact that there has been no evidence of differences in ovarian hormone levels or in cyclical changes in female adolescents with and without STBs is consistent with the previously aforementioned studies in adult women with reproductive mood disorders where the effect of menstrual cycle and/or ovarian hormone levels on STBs in adult women is absent. One interpretation is that it is the

Publication	Sample size and characteristics	Age (years)	Sex	Psychiatric condition	Suicide-related outcome	Study design and methods	Findings	Additional notes
Afzali et al. 2012	81 suicide attempters	Mean = 23.63 SD = 8.41 Range = 15–55	F	Assorted (25 Past mental disorder, 22 Previous suicide attempt)	History of Suicide Attempts	Structured interview over 6 months after attempt	Suicide attempts were not associated with menstrual cycle phase.	Patients with irregular menstrual cycles were excluded.
Baca-Garcia et al. 2010[a]	281 suicide attempters 176 healthy controls	Mean = 30.8 SD = 8.8 Range = 18–92	F	Assorted (229 Mood disorder, 229 SUD, 275 Previous psychiatric treatment)	Recent Suicide Attempts and Recent Suicidal Ideation	Blood sample within 24 h of attempt: estradiol, progesterone, LH, FSH	Suicide attempts were was more likely during the follicular phase. Suicide intent severity was elevated during low-estrogen/low-progesterone states (pre-menstrual phase, amenorreha, menopause)	
Butterfield et al. 2005	130 inpatients	Mean = 49.4 SD = 8.13	M	PTSD	Recent History of Suicide Attempts (past 6 months) and Suicidal Ideation	Blood: DHEA, androstenedione, testosterone, estradiol	Suicide attempters had higher DHEA than nonattempters	
Cayköylü et al. 2004[a]	52 suicide attempters 50 healthy controls	Mean = 26.51 SD = 7.82 Range = Not Reported	F	Assorted (8 PMDD, 1 SCZ, 2 MDD, 1 OCD)	Recent Suicide Attempts	Blood sample within 12 h of attempt: estradiol, progesterone Menstrual status determined with self-report.	Suicide attempts were more frequent during the follicular phase. Estradiol and progesterone levels were not different in suicide attempters compared to healthy controls.	Patients attempting suicide with OD or admitted to the ICU were excluded.
Chatzittofis et al. 2013	28 suicide attempters (10 female, 18 male) 19 healthy controls (7 female, 12 male)	SA: Mean = 44 SD = 14.6 Range = 26–66 HC: Mean = 30 SD = Not Reported range = 23–48	Both	Assorted (14 Mood disorder, 4 Anxiety Disorder, 9 SUD, 19 PD)	History of Suicide Attempts	CSF: DHEA-S, DHEA, cortisol, and 5-HIAA	In males, suicide attempters had higher CSF DHEA-S levels compared to healthy controls. In females, no significant differences.	Exposure to early adversity (e.g., interpersonal violence) correlated negatively with cortisol/DHEA-S ratio
Dogra et al. 2007[a]	217 suicide decedents 237 non-suicide decedents	45% of suicide dececents ages 21–30 Bimodal distribution in the non-suicide decedents: 23% ages 20–25, 23% ages 30–35 Range = 11–45	F	Not Reported	Suicide Death	Autopsy Menstrual status determined by visual examination of the uterine cavity	54.46% of non-pregnant women who died by suicide were menstruating versus 6.75% in the non-suicide decedent group	
Fouriestié et al. 1986[a]	108 suicide attempters	Mean = 25.3 SD = 4.0 Range = Not Reported	F	Assorted (9 with previous psychiatric admission, 15 treated with neuroleptic and/or antidepressant medication, 9 treated with anxiolytics, 15 with previous suicide attempts)	Recent Suicide Attempts	Blood sample within 12 h of attempt: estradiol and progesterone	Suicide attempts were more likely to happen during phases with low estradiol, during the first week of the menstrual cycle (42%) and after the fourth week (12%). Frequency of suicide attempts did not vary significantly during the menstrual cycle in OC users.	Patients admitted to the ICU were excluded.
Gustavsson et al. 2003	43 suicide attempters	Mean = 38.0 SD = 12.0 Range = Not Reported	M	Assorted (14 SUD, 9 DDNOS, 10 MDD, 4 Dysthymia, 9 Adjustment disorder, 4 Anxiety disorder, 2 Psychosis)	Recent Suicide Attempts	CSF in days (5–57 days, mean = 16) following suicide attempt: testosterone	Suicide attempters with depressive disorders showed higher CSF testosterone than those with other psychiatric diagnoses.	CSF testosterone positively correlated with irritability and negatively correlated with social desirability.

Table 1 (continued)

Publication	Sample size and characteristics	Age (years)	Sex	Psychiatric condition	Suicide-related outcome	Study design and methods	Findings	Additional notes
Papadopoulou et al. 2018[a]	70 suicide attempters	Mean = 35.5 SD = 8.9 Range = 18–52	F	Assorted (28 MDD, 13 BD, 14 Psychosis, 15 PD or adjustment disorder)	Recent Suicide Attempts	Blood sample within 72 h of suicide attempt or within 48 h after transfer to the ICU: progesterone, LH, FSH Menstrual status determined with progesterone levels, LH and FSH were used to rule out menopausal status	Suicide attempts were more frequent in the last 4 days of days of luteal phase and during the 4 days of menses.	No effect of menstrual status on lethality (violent vs non-violent mode of attempt) or psychiatric diagnosis.
Markianos et al. 2009[a]	15 suicide attempters (intentional jumps) 18 accident victims (falling from a height) 40 healthy controls	SA: Mean = 39.9, SD = 14.3, Range = 22–62 Non-SA: Mean = 37.6 SD = 15.2 Range = 20–66 HC: Mean = 31.6 SD = 9.0 Range = 25–59	M	Assorted (10 SCZ, 5 MDD)	History of Suicide Attempts	Blood: testosterone, LH, FSH	Suicide attempters had lower levels of testosterone (trending, p = 0.065) and LH compared to accident victims. Both suicide attempters and accident victims had lower levels of testosterone and LH compared to HC.	
Martin et al. 1997[b]	81 female and 79 male adolescents	Mean = 16.0 SD = 1.0 Range = 15–19	Both	Not Reported	History of Suicide Attempts and Suicidal Ideation	Blood: progesterone	In males, progesterone was higher in those with past suicide attempts and with suicide ideation. In females, progesterone levels negatively correlated with past suicide attempts and disclosed suicide ideation	SUD excluded from analyses.
Roland et al. 1986	39 suicide decedents 48 non-suicide (sudden death) decedents	SA: Mean = 39.1 SD = 18.3 Range = 15–76 HC: Mean = 51.5 SD = 13.8 Range = 12–79	M	Not Reported	Suicide Death	Autopsy Blood: testosterone	Suicide decedents showed higher levels of testosterone compared to non-suicide decedents.	
Sher et al. 2012	67 patients with bipolar disorders and at least one past suicide attempt (51 female, 16 male)	Mean = 34.5 SD = 9.9 Range = 18–75	Both	Bipolar Disorder	History of Suicide Attempts	Blood: testosterone	Testosterone levels positively correlated with the number of past suicide attempts, while controlling for sex.	Testosterone levels were also positively correlated with number of manic episodes, while controlling for sex.
Sher et al. 2014	51 patients with bipolar disorder and at least one past suicide attempt	Mean = 33.2 SD = 9.6	F	Bipolar Disorder	History of and Prospective Suicide Attempts (prospective follow-up for up to 2.5 years)	Blood: testosterone	At baseline, testosterone levels positively correlated with the number of suicide attempts and past major depressive episodes. Higher testosterone levels predicted suicide attempts in the follow-up period.	
Sher et al. 2018[a]	17 combat veterans with post-deployment suicide attempt (0 female, 17 male) and 17 non-suicidal combat veterans (2 female, 15 male)	SA: Mean = 37.5 SD = 11.6 Non-SA: Mean = 35.7 SD = 10.8	Both	PTSD	History of Suicides Attempt and Suicidal Ideation	Blood: DHEA, DHEA-S	Suicide attempters had lower levels of DHEA and DHEA-S compared with nonattempters. Suicidal ideation negatively correlated with DHEA and DHEA-S levels across all participants. Suicidal ideation negatively correlated with DHEA-S levels in nonattempters.	DHEA/DHEA-S ratios positively correlate with adolescent and adult aggresion scores in suicide attempters.

[b]Adolescent sample.

neurobiological sensitivity to *changes* in estradiol and progesterone—rather than between-person differences in levels of these hormones—that represents a key trait-like source of variance for understanding suicide risk in the context of puberty, a time when the stability of these hormone dynamics is still in flux [47]. Intensive (e.g., daily samples) longitudinal studies conducted in adult women have also provided little evidence that hormone levels at a single point in time are correlated with levels within the same cycle and also for subsequent cycles, particularly for estradiol [48, 49]. It is also important to note that both between-person and within-person variability of ovarian hormone levels are affected by multiple confounds that investigators ought to consider, including, but not limited, to cycle length [50], diurnal effects [51], cycle phase [48, 49], effects of study participation [48], anovulation [52], culture and/or diet [53], and personal and family medical history (e.g., polycystic ovary syndrome, breast cancer [48, 54]). Nevertheless, dense-sampling studies have demonstrated robust between-person effects of menstrual phase, such that progesterone is reliably higher in the luteal phase relative to the follicular phase and, albeit to a lesser extent, estradiol is higher in the follicular phase relative to the luteal phase [48, 49]. We note in Table 1 which studies employ non-experimental cross-sectional designs and that attempt to relate ovarian hormones without consideration of these relevant factors (e.g., cycle phase).

Given these limitations in measuring ovarian hormones, it is not surprising that little is known about the effects of estradiol and progesterone on the human brain in general, much less on the circuits we have hypothesized are implicated in STB risk. Nonetheless, there is evidence that estrogen receptors are expressed strongly in brain regions involved in social cognition broadly and social rejection specifically, including the amygdala, hippocampus, ACC, and vmPFC [55–58]. Several studies have also found that women with comparably higher levels of estradiol (endogenous or synthetic) show greater amygdala-based resting-state functional connectivity and activation in ACC and vmPFC, which are key regions involved in processing salient information [59–61]. Similarly, longitudinal studies with naturally cycling women have documented larger hippocampal gray matter volumes during periods of relatively high estradiol (late follicular/preovulatory phases) than of relatively low estradiol early follicular/premenstrual phases [62, 63].

There is also evidence from functional magnetic resonance imaging (fMRI) studies wherein groups of women during different phases of their menstrual cycle are compared that show that relatively higher levels of estradiol (pre-ovulatory phase) are associated with greater activation of the hippocampus during both cognitive tasks [64] and affective stress tests [65], and with stronger functional connectivity of the hippocampus with brain regions involved in processing salient information [63]. Similarly, higher levels of progesterone (luteal phase) have also been found to be associated with activation of the striatum and PFC during cognitive processing [64]. Finally, results from fMRI studies utilizing dense-sampling designs of naturally cycling women have reported intriguing, albeit inconsistent, results. One study found no effects of estradiol across the menstrual cycle on intrinsic connectivity patterns [66], whereas another found that higher levels of estradiol drove stronger subsequent connectivity within attention networks (specifically among brain circuits that are implicated in internally focused attentional states and externally focused attentional states) [67]. In contrast, one study found that progesterone mediated patterns of positive functional connectivity between the hippocampus and PFC [66] whereas another study found that higher levels of progesterone was associated with lower connectivity across all networks [67]. It is clear that additional research is needed to clarify the magnitude and directionality of the effects of estradiol and progesterone on patterns of brain connectivity, particularly in adolescents, and their effects on longer-term neurodevelopmental trajectories. It is also critical that researchers work to characterize the extent to which these hormones effect brain circuits specific to STBs, or alternatively, whether they are implicated in mental illness risk more broadly. Nevertheless, the studies we have reviewed provide initial evidence that brain circuits that support the regulation of affectively salient stimuli are sensitive to the effects of estradiol and progesterone; importantly, these same circuits have also been shown to be affected in adults and adolescents with STBs [28, 68].

Additional research is also needed to elucidate the precise neural mechanisms by which estradiol may impact the development of brain circuits, including its effects on neurotransmitters. Estradiol has also been found to alter serotonin transmission, binding, and metabolism by increasing the production of tryptophan and inhibiting the expression of the serotonin reuptake transporter gene (for a review, see [69]). Serotoninergic abnormalities in the number of serotonergic neurons and in serotonin transportation, receptor binding, and levels have all been found in victims of suicide [70, 71] (for a review, see [72]). Serotonin has been shown to be associated with cortisol reactivity to stressors [73] and positively associated with greater 5-HT_{1A} receptor binding—which could contribute to lower serotonin signaling by inhibiting further serotonin release into the synapse—in depressed patients who died by suicide versus both depressed and psychiatrically healthy individuals who did not die by suicide [74]. Similarly, allopregnanolone, a progesterone metabolite, binds to $GABA_A$ receptors, which mediates the majority of inhibitory signaling in the brain [75] and plays an important role in downregulating the

HPA-axis in response to acute stressors [76]. Several studies have found that stress exposure alters the availability of $GABA_A$ receptors as well as their composition and sensitivity to neurosteroid regulation, which, in turn, can influence subsequent responses to stress [77–79]. Emerging data has also implicated GABA dysfunction in STBs, whereby depressed patients who died by suicide showed a higher expression of genes that encode for proteins involved in GABAergic synaptic transmission in the ACC and a lower expression of these genes in the dorsolateral PFC than did both depressed and psychiatrically healthy individuals who did not die by suicide [80]. Future work is needed to explicitly investigate the extent to which patterns of structural or functional connectivity of circuits involving the amygdala, hippocampus, ACC, and PFC that are developing in response to puberty-related changes in estradiol and progesterone (and related neurosteroids) exhibit corresponding changes in neurotransmitter systems that support socioemotional processes relevant to STB risk.

Testosterone

Unlike ovarian hormones, which have been studied primarily in female adolescents, investigators have found in both sexes that levels of androgens are associated with appetitive behaviors, aggression, competition, and other related social behaviors that are relevant to STB risk [81, 82]. In female adolescents, the sex steroid with the most androgenic activity is DHEA, which is produced by the adrenal cortex (discussed separately in the following section); in males adolescents, it is testosterone [31, 32].

In contrast to the data published thus far on ovarian hormones, there is evidence of strong within-person reliability and stability in testosterone levels in both men and women. Indeed, some researchers contend that levels of testosterone are trait-like [83]. Perhaps not surprising, testosterone has been linked more strongly with STB risk, and specifically with suicide attempts, than has any other pubertal hormone (see Table 1). However, the empirical findings thus far have been mixed (for opposing reviews, see [84, 85]). Several researchers have theorized that testosterone is linked to suicidal behaviors through its modulation of emotion-related impulsivity and impulsive aggression, which are considered to be among the most robust predisposing traits to suicidal behaviors in youth [86]. In drawing from the literature of studies in which testosterone is administered and behaviors are subsequently assessed, as well as studies that link changes in social interactions with changes in endogenous testosterone, there appear to be reliable effects of testosterone on socially motivated behaviors, including exerting dominance and displays of aggression (either physically or non-physically) and other social status seeking behaviors (for a review, see [87]). While testosterone exert complex effects on interpersonal behavior, longitudinal studies show that the puberty-related increases in testosterone are not accompanied by a concurrent rise in aggressive behaviors [83, 88, 89]. Additional studies in animals as well as in humans [90] suggest that testosterone levels correlate more closely with social dominance, rather than aggressive behaviors. Hence, testosterone may be an important moderator of the behavioral response to events associated with loss of social status [91], which are known precipitants of STBs. In the context of adolescent STB risk, it may very well be that testosterone is a driver of heightened sensitivity to social context, which can lead to significant emotion dysregulation and impulse control and, in turn, elevated STB risk.

Consistent with these points is evidence that elevated testosterone has also been found in male adults to be associated with psychological states and individual traits associated with suicide risk, including depression severity, irritability, and impulsive aggression [92, 93]. Researchers have found higher levels of testosterone in both male and female suicide attempters than in their same-sex non-attempting counterparts [94], and in post-mortem samples of suicide completers compared to individuals who died from other causes [95]. In a recent study, male, but not female, young adults who attempted suicide had higher levels of testosterone than did age- and sex-matched healthy volunteers [92]. Thus, there studies do not preclude the possibility that testosterone levels are higher in individuals with a mental disorder than they are in healthy persons. One study found in women with bipolar disorder with a history of suicide attempt that higher testosterone levels predicted subsequent suicide attempts [96]. Interestingly, in another sample of men and women with bipolar disorder, higher levels of testosterone were associated with number of suicide attempts only after controlling for sex [97]. In contrast, other studies have found lower levels of testosterone both in male suicide attempters relative to psychiatric healthy controls [98] and in patients who were hospitalized due to accidents [99]. One possible discrepancy for these findings involves the measurement of testosterone in plasma versus cerebrospinal fluid; studies assaying plasma testosterone have typically reported inverse associations with suicide attempts. Nevertheless, it is clear that adequate clinical controls (attempters or completers relative to nonattempters who otherwise have similar clinical histories) must be included in research in order to clarify the results of these studies.

As is the case with research on ovarian hormones and STBs, no studies have examined the psychobiological mechanisms and specific brain circuits through which testosterone may drive risk for STBs in either adolescents or adults. Testosterone influences many of the same neurotransmitters as does estradiol [25]; moreover, testosterone

can be converted into estradiol via aromization [100], adding additional complexity in these processes should be addressed in future work. That said, one pathway through which testosterone may affect mood and cognition is through altering dopaminergic neurotransmission: several studies have found evidence of differences between suicide attempters and completers in dopamine receptor density, transporter binding capacity, and metabolism [101–103], primarily in the striatum. In fact, testosterone receptors are widely expressed in dopaminergic neurons of the striatum and portions of the PFC, including vmPFC and OFC [104]. Research with both macaques and humans has documented changes in the mechanisms that underlie dopamine signaling during adolescence, which may be explained, in part, by effects of testosterone (and estrogen; for reviews, see [105, 106]). In particular, testosterone has been shown to increase basal dopamine levels and decrease the number of enzymes that break down dopamine in the striatum and PFC [105]. Consequently, it is possible that adolescent-typical increases in testosterone during puberty, especially in boys, contribute to elevated STB risk through enhanced dopaminergic transmission. This is consistent with previous reports that, compared to depressed patients who did not die by suicide, depressed patients who die by suicide have lower growth hormone responses to apomorphine [102, 107], which is an indication of higher dopamine transporter binding [108]. Nonetheless, it is important to note that some studies provide evidence of lower dopamine (measured by lower levels of homovanillic acid and total dopamine in urine) in patients who attempted suicide versus those who did not, see [103], or of no significant associations between dopamine levels/receptor binding and STBs [109].

With respect to brain development, higher levels of pubertal testosterone have been associated with white matter organization in tracts implicated in social cognition and emotion regulation, including the uncinate fasciculus (which connects the amygdala and vmPFC) and corpus callosum in both boys [110, 111] and girls [29, 112]. Several researchers have documented other effects of testosterone on adolescent and young adult brain and behavior. Human neuroimaging studies using fMRI have shown that in healthy young men, activation in the amygdala—a brain structure that is rich in androgen receptors [63] and is affected by circulating androgens [64]—to fearful and angry faces co-varies positively with individual differences in serum testosterone concentrations [65, 66] (but see [67] for opposing results). In an experimental study, administration of testosterone was associated with increased amygdala reactivity to threat-related stimuli in young women [113]. These results are consistent with a longitudinal study in adolescents that found that increased levels of pubertal testosterone disrupted typical coupling between the amygdala and OFC, leading to increased amygdala reactivity to threat-related stimuli in both sexes [114]. Finally, whereas in boys higher testosterone levels are associated with lower activation in the striatum and PFC during processing of emotional conflict, in girls higher testosterone levels are associated with lower activation in the PCC/precuneus [115]. Other investigators have shown in both boys and girls that higher levels of testosterone are associated with higher striatal activation during reward consumption [116], and with higher striatal activation when adolescents select smaller yet more immediate rewards [117]. In an observational longitudinal neuroimaging study in male and female adolescents between the ages of 8–27 years, activation in the striatum (nucleus accumbens) to rewarding stimuli peaked during adolescence, and was associated with accompanying changes in testosterone levels [118]. In a recent study, in which salivary testosterone was measured in adolescents before and after a neuroimaging scan, acute increases in testosterone were associated with smaller differences in activation between reward cues signaling reward or non-reward outcomes for a given trial in vmPFC and posterior cingulate cortex (PCC) in both sexes [119]. Thus, by altering neural processing of both negative (e.g., threatening) and positive (e.g., rewarding) valenced stimuli, testosterone may be facilitating the expression of adolescent sensation-seeking and risk-taking behavior [118] through dopaminergic transmission among these subcortical and prefrontal circuits. Certainly, these processes may not be specific to STBs and may represent a more general diathesis for mental disorders that are characterized by sensation-seeking and risky behaviors; however, future research is needed to test this possibility more explicitly.

In sum, studies to date have demonstrated that higher levels of testosterone are associated with aspects of emotion-related impulsivity in males with a history of suicidal behaviors (e.g., attempts). Higher levels of testosterone are also associated with steeper temporal discounting of rewards driven by patterns of activation in striatal, vmPFC, and OFC in both sexes; sex differences in the effect of testosterone on adolescent brain circuits appear to be most prominent in emotion-related contexts. Indeed, in adults, both endogeneous levels [120] and exogenous administration [121] of testosterone enhance risk taking. The predisposition to take risky decision has been shown to be a critical risk factor for suicidal behavior in adults [122] and, to a lesser extent given the sparse literature on this topic, in adolescents [123]. Hence, functional alterations in decision-making systems induced by puberty-related rises in testosterone levels, or their context-dependent fluctuations, might be related to suicidal risk through an increase probability of perpetrating highly risky and self-destructive behaviors in the face of overwhelming stress (particularly social stressors involving loss of desired status). Future work is needed to test explicitly whether higher levels of testosterone exacerbate affect

striatal and PFC systems underlying maladaptive responses to social stressors that, in turn, lead to heightened risk for STBs.

DHEA

DHEA (and its sulfate, DHEA-S) is the most abundant steroid hormone in humans and is a precursor to sex steroids. Researchers have not yet examined the relation between DHEA (or DHEA-S) and STBs in adolescents; moreover, and the few studies that have been conducted with adults differ in their measurement of DHEA. One study showed that male suicide attempters had higher levels of DHEA-S than did healthy controls, and that exposure to extreme social threat (i.e., interpersonal violence) as a child was negatively correlated with the ratio of cortisol/DHEA-S [124]. Among adults diagnosed with PTSD, those who had attempted suicide had significantly higher levels of DHEA than did those without a history of attempt [125]. Another study found that, in combat veterans, the ratio of DHEA/DHEA-S was positively correlated with total adolescent aggression scores, total adulthood aggression scores, and lifetime aggression scores in those who had attempted suicide but not in nonattempters [126].

Overall, these studies suggest that higher levels of DHEA or DHEA-S may be associated with risk for STBs. Indeed, DHEA modulates neurotransmitter systems implicated in suicidal thoughts and mood disturbances, including acting as an antagonist for GABA receptors, with genes widely expressed in hippocampus, amygdala, and striatum [127]. There is also intriguing evidence that psychiatric conditions characterized by excessive stress and elevated suicide risk lead to a downregulation of neurosteroid biosynthesis—including the conversion of DHEA to GABAergic metabolites, such as allopregnanolone [128]—and changes in $GABA_A$ receptor subunit composition [129]. Thus, STB risk may be associated with higher levels of DHEA due to an insufficient ability to metabolize DHEA. With respect to the effects of DHEA on the adolescent brain, however, there have been a small number of studies. Thus, far investigators have found that higher levels of DHEA are associated with larger hippocampal volumes in both male and female adolescents [130] and with lower white matter organization across a broad set of white matter tracts [110]. Other studies have found that higher DHEA levels are associated with reduced cingulate activation and greater functional connectivity between the amygdala with ACC and other regions involved in processing salient information in adolescents during the processing of social stimuli (e.g., viewing fearful faces) [131]. Moreover, higher DHEA levels are associated in girls with lower activation in cingulate regions implicated in processing salience information and with greater externalizing problems [132], but in boys with stronger functional connectivity between the amygdala and inferior frontal gyrus (the opposite pattern was found in girls) and with higher anxiety symptoms [131].

Despite the heterogeneity in clinical, developmental, and demographic features across the studies reviewed in this section, there appear to be consistent associations between higher levels of DHEA and both STBs and altered structure and function of brain circuits underlying emotion regulation. In adults with clinical disorders, higher levels of DHEA (either alone or relative to cortisol) appear to be associated with STBs. In psychiatrically healthy adolescents, higher levels of DHEA are associated with reduced downregulation of affective signals in the amygdala from emotion regulatory cortical regions, including the ACC and portions of the PFC. Thus, higher levels of DHEA may disrupt the development of emotion regulatory brain circuits across adolescence in ways that increase risk for STBs when individuals are exposed to interpersonal stressors (particularly those characterized by threat). However, it is worth noting one study of psychiatrically healthy adults in which administration of exogenous DHEA reduced activation in the amygdala and hippocampus, increased activation in the vmPFC, and led to stronger connectivity between the amygdala and hippocampus during an emotion reappraisal task; moreover, decreased activation in the hippocampus during the task was associated with lower negative affect, suggesting that higher levels of DHEA improve negative mood by downregulating affective signals in the hippocampus [133]. Additional research is needed to examine whether these associations hold in clinical samples of adolescents and whether (or how) they are related to risk for STBs.

Consideration of sex differences

Across most countries, being female increases the risk of suicidal thoughts and related behaviors [5]. Despite this higher prevalence of STBs in women, men are more likely to die by suicide [134], leading to "the gender paradox of suicide." It is notable that the sex difference in suicide deaths increases dramatically in adolescence [135], suggesting that puberty plays an important role in explaining this difference (although this sex difference is now narrowing among adolescents [136], indicating that other factors, including environmental or cultural influences, are also likely). Whereas past-year ideation, plans, and attempts tend to peak during mid-adolescence (~16 years) in girls, these rates increase steadily throughout mid- to late adolescence in boys [137, 138].

As in adults [5, 139], there are sex differences in suicide-related outcomes in adolescents that are mediated in part by differences in lethality and mental illness. In a psychological autopsy study, adolescent male suicide victims were

more likely to use lethal methods and had a higher prevalence of conduct disorder than did female victims [140]. A recent meta-analysis of sex-specific suicide risk in adolescents (ages 12–26 years) found distinct clinical and environmental risk factors for suicide attempt in male and female adolescents [139]. Thus, in addition to the hormonal differences that underlie sex-specific neurodevelopmental changes, different clinical conditions (externalizing disorders in boys versus mood disorders in girls) and social stressors (peer influence in boys versus direct trauma/victimization from romantic relationships in girls) may further explain or moderate these pathways to risk for STBs. Because of the sparse literature, however, it is not clear whether sex-specific risk factors are present before puberty, whether puberty affects neuroendocrine systems in sex-specific ways to increase risk for STBs, or whether boys and girls are exposed to differential environmental risk factors as a result of going through puberty. Future research should attempt to clarify the extent to which pubertal processes play a central role in STBs or whether they are implicated in mental illness more generally.

While adrenal and gonadal hormones and physical maturation are important indicators of pubertal development, other aspects of puberty may be relevant in the context of adolescent risk for STBs. Pubertal timing—the age at which individuals mature relative to their peers [141]—has been linked to individual differences in mental disorders in adolescence [142, 143]. Moreover, the timing of pubertal onset may have a different impact on developing neuroendocrine function depending on whether it occurs earlier or later in a given individual [34, 139]. Given that girls typically enter puberty earlier than do boys, considering the role of pubertal timing may also elucidate sex differences in risk for STB—as well as mental illness more generally—and accompanying endocrine and neural processes. A growing number of studies are reporting that early menarche is associated with elevated risk for suicidal ideation in adolescent girls [144–146]. In a recent longitudinal study of a large birth cohort, earlier age of menarche was associated with increased suicidal behaviors at 16 and 21 years of age [147], suggesting that earlier puberty has an enduring effect on STB risk throughout adolescence and young adulthood. In addition, considerable evidence suggests that pubertal timing is influenced by early life adversity [148], which itself is a robust predictor of STBs [149]. Thus, early puberty resulting from early adversity may be a mechanism by which suicide risk is instantiated or exacerbated in vulnerable adolescents. Finally, it is important to acknowledge that sexual orientation and identification as a sexual minority are increasingly being recognized as risk factors for STBs [150]; more research in this area is critically needed.

Future directions

No research has yet examined whether and how pubertal hormones affect neurodevelopmental trajectories of brain circuits that mediate social cognition and emotion-related impulsivity explain risk for STBs during adolescence. Studies are needed to clarify the role of pubertal timing and the multidimensional mechanisms—biological, social, cultural—by which puberty-related processes influence risk for STBs. An important next step for the field is to first establish reliable associations between pubertal hormones and adolescent brain structure and function and to then map those associations onto neural circuits underlying STBs in adolescents. Other critical knowledge gaps include disentangling neuroendocrine mechanisms that are more closely linked to suicidal thoughts versus attempts (and other self-harming behaviors) and that facilitate the transition from ideation to action [151].

Although we focused here on the effects of pubertal hormones, we should acknowledge that there is considerable evidence that HPA-axis dysfunction is associated with STBs and self-harming behaviors in adolescents [13, 21, 152, 153]. Puberty is also the time when HPG-axis regulation of the HPA axis develops [154–157]. Given that the expected suppression of the HPA axis by the HPG axis [158] is disrupted in individuals at risk for STBs (due to such factors altering developmental changes in stress response and regulatory systems, including experiences of adversity and exposure to trauma during early life [154]), it is critical that researchers explicitly examine the role of puberty in this context.

It is also important that researchers in this area consider moving away from a nomothetic framework for the prediction of STBs and instead adopting idiographic or person-centered models. Puberty is a highly individualized process; adolescents differ markedly in their hormone levels, their neurobiological sensitivity to typical endocrine changes [14], their pubertal timing, their neurodevelopmental trajectories, and their psychological responses to maturation. Certainly, measuring these variables at the individual level is challenging and will have to take into account population norms on several dimensions (e.g., ethnicity, socio-demographic factors). Absent such data, standardization within age bands or residualized scores (e.g., regressing pubertal stage on age to obtain a measurement of pubertal timing) can be used to capture individual variability (for a treatment of these issues, see [159]). Another solution is to use "dense sampling" approaches that leverage repeated assessments (e.g., self-reported mood states, saliva samples, neurobiological measurements) from the same individual in order to capture intra-individual variation in these processes [13], which we argue is critical for understanding the contribution of ovarian hormones in risk for STBs in adolescent

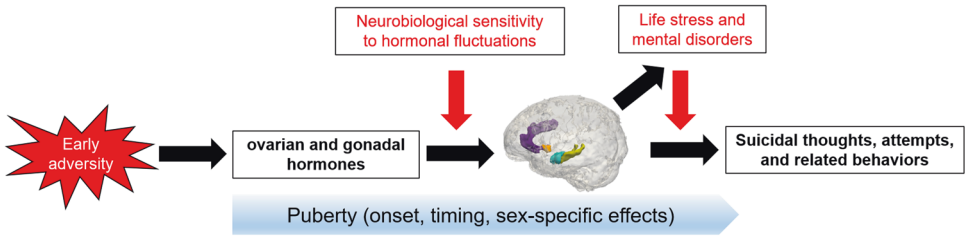

Fig. 2 Conceptual model linking aspects of the pubertal transition with risk for suicidal thoughts and behaviors. Experiences of early adversity affect the programming and development of endocrine and neural systems which undergo significant maturation during puberty. Puberty-related changes in ovarian, gonadal, and other related hormones shape the neural circuits underlying social cognition, emotion regulation, and impulse control (which include structures such as the amygdala, hippocampus, striatum, anterior cingulate cortex, and portions of prefrontal cortex). Alterations in these circuits may partially explain the ways in which changes in sex hormones are linked with the emergence of suicidal thoughts and behaviors during adolescence. Moderators of these processes, including a neurobiological sensitivity to ovarian hormones, experience of ongoing life stressors, and underlying mental disorders, are highlighted in red.

females. Dense-sampling has the additional advantage of being able to identify proximal factors that lead to suicidal states and other related high-risk events, which are often transient and rarely captured in the laboratory or clinic [160].

Other important study design considerations include larger sample sizes of both sexes in order to detect sex differences more reliably. As we alluded to in the earlier sections of our review, there are other important confounds to consider that will affect the reliability and validity of estimating the effects of within-person changes in sex hormones on brain and behavior. These confounds include genetic factors, environmental influences, medical conditions, and cycle length (given that the range of menstrual cycles and periods of anovulation are longer in adolescents than in adults, particularly in the first few years post-menarche [161]). Finally, understanding the normative associations between changes in hormones with the structural and functional development of the brain is a critical next step that must be established before understanding how these alterations are altered in individuals at risk for STBs. Gaining a more comprehensive understanding of neurobiological trajectories and the mechanisms of neuroplasticity in adolescents as a consequence of puberty will also contribute to our knowledge of sex-specific psychiatric interventions and may help to address the heterogeneity of risk factors identified to date [5]. For instance, the granularity of data obtained from dense-sampling methods will facilitate the identification of individuals with hormonal sensitivity to the typical fluctuations occurring during puberty, as well as characterize within-person pubertal processes associated with responses to social stressors and poorer impulse control during heightened emotional conflict. With this information, researchers and clinicians will be able to stratify individuals on the basis of neuroendocrine risk (e.g., those with hormone sensitivity) and also to identify points in time (e.g., dramatic increases in stress perception or depressive symptoms, unusual variability in DHEA) during which an individual might benefit from immediate intervention.

Summary and conclusions

Globally, suicide has surpassed all physical diseases as a cause of death in adolescents. Puberty drives psychobiological changes in adolescence that have not been examined explicitly in relation to suicide risk. In this review, we conceptualized suicidal thoughts and behaviors in adolescents as resulting from pathological responses to social stressors at a time when stress-regulatory systems are still maturing. We argued that alterations in brain circuits—comprised of connections among the amygdala, hippocampus, striatum, ACC, vmPFC, and OFC—that underlie social cognition, emotion regulation, and impulse control and are shaped by puberty-related changes in sex hormones. We propose that alterations in these circuits may partially explain the ways in which changes in sex hormones are linked with increased suicidal thoughts and behaviors during adolescence. However, we also highlighted critical moderators to be considered in this model, including a neurobiological sensitivity to fluctuations in ovarian hormones, exposure to early adversity, and underlying mental disorders (Fig. 2). To date, these specific hypotheses have not been tested. Although there is emerging research identifying shared and unique neural circuits that underlie suicidal thoughts and behaviors [68], it is paramount that that these associations be examined in prospective studies. It will also be important to use both experimental designs and large-scale longitudinal studies to elucidate the extent to which pubertal hormones affect the acute functioning of these circuits and drive the development of these circuits over the course of adolescence and young adulthood. Moreover, we expect that although pubertal hormones are not a primary driver of suicide risk, they may play an outsized role in individuals with a neurobiological sensitivity to hormonal fluctuations. Therefore, it is critical that we identify key moderators of the paths in our model, which we hypothesize includes neurobiological sensitivity to hormonal fluctuations, experiences of adversity and life

stress that influence neurodevelopmental trajectories (which, in turn, may result in generating and experiencing additional stress), and underlying mental disorders. In addition to conducting longitudinal studies with larger sample sizes, we suggest that researchers also use dense-sampling methods to identify individuals according to these stratification parameters (e.g., hormonal sensitivity), as well as points in time at which individuals may be at risk and could benefit from more immediate intervention. In conclusion, we want to emphasize that increasing our understanding of pubertal science across endocrine, neural, and psychosocial domains will yield significant insights concerning how best to reduce the frequency of suicide-related deaths during the vulnerable period of adolescence.

Abstract

As the proverbial creatures of habit, people tend to repeat the same behaviors in recurring contexts. This review characterizes habits in terms of their cognitive, motivational, and neurobiological properties. In so doing, we identify three ways that habits interface with deliberate goal pursuit: First, habits form as people pursue goals by repeating the same responses in a given context. Second, as outlined in computational models, habits and deliberate goal pursuit guide actions synergistically, although habits are the efficient, default mode of response. Third, people tend to infer from the frequency of habit performance that the behavior must have been intended. We conclude by applying insights from habit research to understand stress and addiction as well as the design of effective interventions to change health and consumer behaviors.

INTRODUCTION

The yin and yang of the history of habits is closely tied to broader trends in the history of psychology. William James's (1890) view that "habit covers a very large part of life," necessitated that we "define clearly just what its limits are" (p. 104). Psychology complied, and the habit construct acquired specific meanings in the behaviorist traditions of Thorndike's (1898) law of effect, Hull's (1943) formalized drive theory, and Skinner's (1938) operant conditioning. However, these reinforcement-based models of habit were soon supplanted as the field embraced more purposive and cognitive perspectives. To Tolman (1948), repeated behaviors reflected learning of internal representations and maps, and Miller et al. (1960) argued that habits be replaced with information-processing mechanisms of goal pursuit. Accordingly, cognitive psychology and decision-making research in the 1960s and 70s developed largely separately from research on habit.

More recent theories have captured the complexity of action control and enabled integration of these opposing conceptualizations. The concept of automaticity (Shiffrin & Schneider 1977) and theories of dual information processing (Wason & Evans 1975) provided frameworks inclusive of habits and thoughtful decision making. Through procedural memory, habits could be cognitively represented as distinct from other types of implicit processes as well as from explicit, declarative memories (Squire & Zola-Morgan 1991). Reinforcement learning (RL) research with animals identified a behavioral criterion for detecting habit performance, involving insensitivity to changes in rewarding outcomes (Dickinson 1985), and neuroscience began to identify the brain regions and circuits involved in habitual behavior (Graybiel 1998). Social-cognitive approaches outlined a variety of ways in which habits interface with goals (Verplanken & Aarts 1999, Ouellette & Wood 1998), and computational models included goal pursuit and prospective planning as

well as habit-like mechanisms of stimulus-driven or model-free action control (Cooper et al. 2014, Daw et al. 2005). Empirical fuel for the study of habit was provided by evidence of the high levels of repetition in daily activities (Khare & Inman 2006, Wood et al. 2002). Further framing these developments is the reading public's interest in understanding their own habits (e.g., Rubin 2015).

In this article, we take stock of the fast-growing research on habits. Our review is necessarily wide reaching, covering a variety of behavioral domains, cognitive tasks, and neuroscientific findings. We also consider animal learning research when relevant, given that habit learning mechanisms are largely conserved across mammalian species and do not appear to be degraded in humans or replaced by higher cortical functions (Bayley et al. 2005). Across these diverse research paradigms, the common elements are habit learning through repeated responding so as to form context-response associations in memory, and automated habit performance that is relatively insensitive to changes in the value or contingency of response outcomes. As we explain, these definitions of habit learning and performance capture the cognitive and neural mechanisms involved in habit memory and are reflected in characteristic patterns in habitual responding.

The schematic in **Figure 1** provides a framework for this review by depicting three ways in which habits interface with goals to guide behavior. Goals energize and direct action by defining a desired end state. In our three-pronged model, habits and goals interact through habit formation, habit performance, and inferences about the causes of behavior. First, goals influence habit formation by initially motivating people to repeat actions and to expose themselves to performance contexts (see Habit Formation section). This is illustrated by the arrows from goal system to context cues and habitual response in **Figure 1**. Once habits form, context cues come to automatically activate the habit representation in memory (see Habit Automaticity section). Second, people act on the habit in mind as well as on their prevailing goals by tailoring their behavior to the current circumstances (see Computational Models section). External factors such as stress and distraction influence the impact of these two processes by reducing the motivation or ability to deliberately pursue goals and increasing reliance on habits (see section Factors that Shift the Balance Between Habits and Goals section). As outlined in dual-process frameworks, habits provide a sort of default response unless people are sufficiently motivated and able to tailor their behavior to current circumstances. Finally, people make inferences about their goals based on observing their own frequent behavior, as reflected by the double-headed arrow in **Figure 1** between the habitual response and the goal system (see Inferences about the Causes of Habit Performance section).

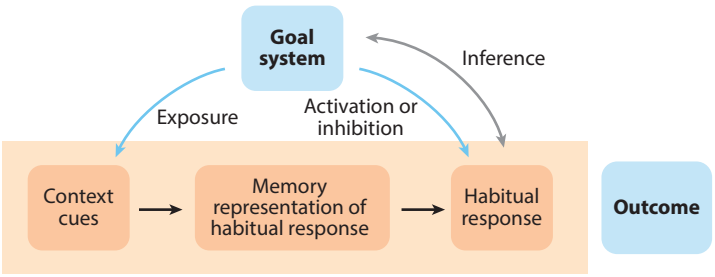

Figure 1

Schematic of three ways in which habits interface with deliberate goal pursuit: through initial repetition and exposure to contexts during habit formation (illustrated by the arrows from goal system to context cues and habitual response), through activation or inhibition of the habitual response, and through inferences about the probable causes of habit responding (reflected by the double-headed arrow between habitual response and goal system).

To conclude the review, we apply insights from basic research on habit to understand stress and addiction and to design successful behavior-change interventions (see Changing Habits section).

HABIT AUTOMATICITY

The terms habit and automaticity are sometimes used interchangeably. Like other automatic responses, habits are activated in memory in an autonomous fashion without requiring executive control (Evans & Stanovich 2013). Habits, however, are not synonymous with automaticity but are best understood as learned automatic responses with specific features (Wood et al. 2014). Two defining features of habit automaticity are (*a*) activation by recurring context cues and (*b*) insensitivity to short-term changes in goals (a.k.a., not goal dependent), including changes in the value of response outcomes and the response-outcome contingency. Additional features that apply to most habitual responses include speed and efficiency, limited thought, rigidity, and integration of sequences of responses that can be executed as a unit (Seger & Spiering 2011, Smith & Graybiel 2013). However, each of these additional features may not be assessed in all habit research paradigms. Instrumental learning studies, for example, often do not evaluate response speed, whereas learning of motor sequences in cognitive-experimental research is assessed primarily via changes in response latency.

Habits differ from other automatic, implicit processes including priming, classical conditioning, and nonassociative learning (Evans & Stanovich 2013, Squire & Zola-Morgan 1991). For example, the priming of goals, attitudes, or concepts can activate a range of responses, not only the repetition of a particular well-learned response (see Wood et al. 2014). Even strongly desired goals that stably characterize people's motives do not necessarily yield stability in the particular means of goal pursuit. In contrast, habit automaticity applies to a specific response. Furthermore, unlike habits, automated goals (e.g., implementation intentions) influence behavior primarily to the extent that they are consistent with people's explicit motivations (Sheeran et al. 2005).

Automatic Cuing of Habits

A variety of cues might trigger habit performance, including aspects of physical environments, other people, and preceding actions in a sequence. Once habits form, perception of the relevant context cues automatically activates the mental representation of the habitual response. Exposure to cues might be deliberate, as when sitting at a computer in order to activate thoughts of work. Or exposure can be inadvertent, as when a chance sighting of a fast-food outlet activates thoughts of eating. We assume that the memory representation of a habit response is cognitively richer than a mere motor program that controls response execution. Given that human cognition is based on integrated sensorimotor units (Hommel 2009), a habitual response will be represented in terms of response features as well as perceptual features. Specifically, the sensory feedback while making a response, which gives rise to the experience of performing the action, is included in the mental representation. As a consequence, a habit cue not only triggers a motor program, it also activates a multimodal representation, or thought, of the habitual response. Consistent with this view, Neal et al. (2012) found that runners with strong running habits automatically brought to mind thoughts of running and jogging when exposed to words designating the physical locations in which they typically ran.

Once habitual responses are activated, people can act on the response in mind without making a decision to do so. That is, habit performance follows relatively directly from the perception of context cues and thoughts about the behavior, reflecting the tight linkage between an internal action representation and the action itself (James 1890). For example, when students who

frequently went to the sports stadium on campus were incidentally exposed to an image of the stadium, they raised their voices as they would habitually in that context, despite no change in their motivation to speak loudly (Neal et al. 2012). Also, in a study conducted in a local cinema, participants with stronger habits to eat popcorn at the movies consumed more than those with weak habits, even when they disliked the popcorn because it was stale and unpalatable (Neal et al. 2011). However, when in a campus meeting room watching music videos, participants with strong cinema-popcorn eating habits were guided by their preferences and ate little stale popcorn.

Habit performance is typified by the insensitivity to outcomes apparent in speaking loudly in a quiet laboratory setting and eating popcorn despite disliking it. This insensitivity has been demonstrated directly in instrumental learning experiments in which participants were first trained extensively to choose a reward to a certain image cue (e.g., Tricomi et al. 2009). Participants then ate as much of the reward as they desired, so that they did not want any more of that specific food. Nonetheless, when tested again, extensively trained participants in this paradigm continued to make the habitual but unwanted choice to the associated image (see also Hogarth et al. 2012b, Schwabe & Wolf 2010).

Triandis's (1977) early work on behavior prediction sparked social psychologists' interest in the idea that repeated behavior becomes more habitual and less dependent on goal pursuit. In prediction studies, behavioral intentions and habit strength (usually operationalized as frequency of past performance) are used to predict future performance. In a meta-analysis of 64 such studies, Ouellette & Wood (1998) found that intentions were stronger predictors of actions that were performed only occasionally (e.g., getting flu shots) than actions that could be repeated more regularly (e.g., wearing seat belts). Actions performed regularly apparently became habitual and persisted with little guidance from intentions (see also Gardner et al. 2011). In addition, habits and intentions interact in guiding daily variations in behavior. For example, on days when participants' intentions to engage in physical activity were weaker than usual, they fell back on their exercise habits and worked out only to the extent that exercise was habitual (Rebar et al. 2014). Also, in a longitudinal test, habit strength to donate blood determined the relation between intentions and actual donations (P. Sheeran, G. Godin, M. Conner, and M. Germain, unpublished data). That is, for participants with weak donation habits, increasingly favorable intentions predicted a greater number of future donations. However, as habit strength increased, the predictive power of intentions diminished, and participants with the strongest habits simply repeated their past donations without input from intentions.

When acting out of habit, the ready response in mind reduces deliberation and narrows focus even when some explicit decision making is required. In a multiattribute choice task involving a series of travel mode decisions, participants with stronger habits to ride a bike or drive their car conducted less extensive information searches, considered fewer action alternatives, and biased the searches toward their habitual choice (Aarts et al. 1997; see also Betsch et al. 2001). Experimentally enhancing attention to the decision process temporarily increased alternative choices, but the habitual choice reemerged with continued decisions (Verplanken et al. 1997). These results may in part reflect that the repeated activation of one response in a context reduces the cognitive accessibility of alternatives (Danner et al. 2007). Essentially, people with strong habits process information in ways that reduce the likelihood that they will consider acting otherwise.

Habit Automaticity and Deliberation About Action

Dual-process theories of decision making and judgment outline the mechanisms that lead people to respond automatically or to engage in deliberate information processing that draws on the limited-capacity resource of working memory (Evans & Stanovich 2013). From this view, people

REVIEWS IN ADVANCE

Annu. Rev. Psychol. 2016.67. Downloaded from www.annualreviews.org
Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

often act habitually in the interests of efficiency (Wood et al. 2014). When motivated and able to engage in deliberate goal pursuit, however, they might identify desired outcomes, set and initiate behavioral intentions, end actions, and evaluate outcomes (Gollwitzer & Brandstätter 1997).

Dual-process models in psychology often specify that automatic and deliberate systems interact through a default-interventionist architecture (Evans & Stanovich 2013) so that responses are largely habitual unless the deliberative system intervenes to impose an alternative. In contrast, reinforcement-learning computational models of routine behavior and decision making (see Computational Models section) often invoke the less psychologically plausible parallel-competitive form of dual-process architecture, in which planning proceeds in parallel with habitual control. As Evans & Stanovich (2013) point out, parallel processing assumes that a costly central executive is almost continuously ready to be engaged in planning and deliberation. More recently, some computational models have adapted a more default interventionist approach in which planning intervenes to alter habits only when necessary (e.g., Pezzulo et al. 2013). It is useful to note that, although we invoke the dual-process framework in this review, action control is influenced by more than two processes, including automated goal pursuit (Sheeran et al. 2005) as well as Pavlovian conditioning of incentive motivation (Balleine & O'Doherty 2010).

In summary, perception of habit cues automatically activates habit representations, and people typically carry out the habit in mind. Thus, behavior prediction studies reveal that people often act out of habit, even when it is in conflict with their intentions. In dual-process models depicting the ways that habits integrate with goals in guiding behavior, habits are a ready default unless people are motivated and able to intervene and engage in more deliberate goal pursuit.

HABIT FORMATION

Given that everyday habits develop as people go about pursuing life goals, habit formation is closely intertwined with goal pursuit. Nonetheless, an implication of the basic context-response mechanism underlying habits is that behavior becomes less responsive to current goals and planning as habit associations strengthen.

Habits develop through instrumental learning and build on the fundamental principle that rewarded responses are repeated (Thorndike 1898). When repeatedly pursuing a goal such as making coffee, people experience covariations between context cues (e.g., coffee filter) and actions (e.g., measure grounds) that lead to goal attainment. Daily life is full of such repetition. In experience-sampling research in which people recorded once per hour what they were thinking, feeling, and doing, about 43% of actions were performed almost daily and usually in the same context (Wood et al. 2002; see also Khare & Inman 2006). Particular actions, such as types of food eaten, also tend to be performed in particular physical locations (Liu et al. 2015). Typically, the learning of context-response associations is an unintended consequence of this repetition. Suggestive of this automaticity, participants in Wood et al.'s (2002) study often reported that they did not think about repeated behaviors during performance.

Associative and Reward Mechanisms in Habit Learning

Habits strengthen through associative and reward-learning mechanisms that capture the slow, incremental nature of habit formation. With each repetition, small changes occur in the cognitive and neural mechanisms associated with procedural memory. Through Hebbian learning of repeated connections, cognitive associations between context cues and a response are strengthened gradually so that people are prepared to repeat performance when the context cues are encountered again (called direct cuing by Wood & Neal 2007).

REVIEWS IN ADVANCE

Changes may still occur before final publication online and in print

Annu. Rev. Psychol. 2016.67. Downloaded from www.annualreviews.org
Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

The strength of context-response associations is further modulated by the reward following the response. At a neural level, midbrain dopamine systems support this reinforcement process. By signaling reward prediction errors, or the discrepancy between an anticipated and actual reward, a phasic dopamine response acts as a teaching signal for habit learning in the striatum (Balleine & O'Doherty 2010). Specifically, the dopaminergic signal that is triggered by an unexpected change in reward magnitude works retroactively to stamp in associations between the still-active memory traces of the response and the cues in the performance context (Wise 2004). Thus, dopamine signals promote habit learning as people initially repeat responses to a reward, but the signals become less active with repetition, as the reward recurs.

In computational RL models, habit formation is conceptualized as the learning of value signals that represent the expected future rewards for the different response options in a given context and provide the basis for selecting an action (see Computational Models section). Value-based selection of habitual responses can be can be regarded as a form of motivated cuing (Wood & Neal 2007).

Another way in which habitual responding continues to be influenced by motivational processes is through context cues that have become associated with the reward that follows an action. As learned predictors of reward, such Pavlovian context cues can cause the habitual response to be performed with increased vigor (Balleine & O'Doherty 2010). Of note, the motivational effect of such Pavlovian predictors of rewarding outcomes is distinct from the motivational value of the outcome itself. Holland (2004), for example, found that responses extensively trained into habits were insensitive to changes in outcome value but continued to be influenced by reward-related cues.

A standard finding from animal learning is that habits develop most readily when rewards are provided on interval schedules, meaning that responses are rewarded only after a time has elapsed. Such rewards mimic natural resources that are replenished over time. With these schedules, changes in response rate during the time interval do not change the amount of reward delivered, reducing the experience of instrumental contingency between the response and the reward (Dickinson 1985). Thus, interval rewards likely promote habit learning because context-response associations can form without including a representation of the goal or outcome of the action.

As a caveat to the principle that habits form from repetition, habits do not always emerge with complex tasks in which different response choices lead to different rewards. In animal research, even after extensive training at a task involving a lever press (yielding sucrose) or chain pull (yielding a food pellet), rats failed to form habits—they continued to be sensitive to reward value and ceased responding for one of these rewards after it had been paired with a toxin (Colwill & Rescorla 1985). Perhaps in an analogous fashion, decision making in humans impedes habit formation. In a repeated sequential choice task, participants failed to form habits to the extent that they spontaneously used a planning strategy and based their choices on the value and probability of response outcomes (Gillan et al. 2015). Similarly, habit formation was hindered when an instrumental task promoted planning compared with mapping of responses to cues (Liljeholm et al. 2015). It appears, then, that deliberative decision making is protective against habit formation even when people respond repeatedly to particular cues.

In summary, habits are likely to form from responses repeated contiguously with context cues, especially when responses are rewarded on an interval schedule. Through the activation of dopamine systems, habits form that are insensitive to current shifts in reward value and structure. However, planning and making deliberate choices during responding can hinder habit formation.

Measures of Habit Strength

Habitization is a process, with no clear demarcation point when strong habits have formed. Nonetheless, instrumental learning tasks provide a clear behavioral criterion. That is, habits have

REVIEWS IN ADVANCE

Changes may still occur before final publication online and in print

Annu. Rev. Psychol. 2016.67. Downloaded from www.annualreviews.org
Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

formed when participants continue to repeat a well-practiced response after the reward has been reduced in value (e.g., for food rewards, after consuming to satiety) or is no longer tied to the response (Dickinson 1985). In these paradigms, habitual responding is evaluated during a subsequent extinction phase (rewards withheld) in order to preclude additional learning based on the changed reward values.

Behavioral indicators of habit strength are captured in a variety of experimental paradigms beyond the simple motor responses often thought emblematic of habits. Habit strength has been manipulated in experimental paradigms involving word-association tasks (Hay & Jacoby 1996, Quinn et al. 2010), choice tasks involving pictorial and other judgment stimuli (de Wit et al. 2009, Gillan et al. 2015), two-stage decision-making tasks (Daw et al. 2011), and problem-solving tasks such as tower building (Patsenko & Altmann 2010). Strong habits also have been formed as humans repeatedly navigate through virtual mazes (Marchette et al. 2011) and rats through actual mazes (Packard & Goodman 2013). Echoing insensitivity to reward, strong habits in these paradigms often emerge as errors, reflecting persistent responding despite task changes in the correct, rewarding outcome. Habits also emerge as chunked responses into a unit (Dezfouli & Balleine 2013, Graybiel 1998), which is related to the performance gains (reduced response time, increased accuracy) in many sequential learning tasks (e.g., Lungu et al. 2014). In addition, eye-tracking measures have been used to capture visual attention to task structures triggering habitual responses (Patsenko & Altmann 2010).

The strength of everyday habits is typically assessed from people's self-reports. One method is to combine self-reported ratings of behavioral frequency with ratings of the stability of the performance context, reflecting the logic that habits represent the repeated pairing of responses and recurring context cues (Galla & Duckworth 2015, Wood & Neal 2009). Using an alternative approach, the Self-Report Habit Index estimates habit strength from a questionnaire measure of the experience of automaticity and frequency of past performance (Verplanken & Orbell 2003), which has further been streamlined to measure only automaticity (Gardner 2014, Gardner et al. 2012). However, as Labrecque & Wood (2015) noted, experienced automaticity measures often fail to assess triggering contexts and may capture automation more generally, as opposed to habit automaticity that guides performance with limited input from current intentions. However, these measures can successfully capture habit strength when triggering cues are present (P. Lin, W. Wood, and J. Monterosso, unpublished data). Perhaps the most valid assessments of everyday habit strength involve reaction time measures of the accessibility of the habitual response given exposure to associated context cues (e.g., Neal et al. 2012).

In summary, assessments of habit formation rest most importantly on evidence that responses are insensitive to changes in rewarding outcomes. Habit formation has been documented in a variety of laboratory tasks using a variety of behavioral assays. For everyday habits, self-report assessments can capture habit strength, although direct assessment of context-response associations is probably most effective.

COMPUTATIONAL MODELS

Computational models offer detailed accounts of the cognitive processes that support habit learning and performance. We selectively focus on models that incorporate habit-like control systems as well as deliberate goal pursuit. Instead of making the simplified assumption that a behavior is either goal directed or habitual, these models explore how adaptive behavior can emerge from the interplay of different models of action control. Competing ideas have been proposed about how the different action controllers work together to produce a response.

In Cooper et al.'s (2014) goal circuit (GC) model, goals structure the learning of habits and control their expression. The GC model is an artificial neural network composed of two interlinked

REVIEWS IN ADVANCE

Changes may still occur before final publication online and in print

habit and goal subnetworks. The habit system, which was originally proposed by Botvinick & Plaut (2004), selects actions in a bottom-up manner based on the current stimulus environment and on internal feedback about the network's previous state. This response selection process is biased by input from the goal system. A habit develops gradually as the network repeats the same sequence of responses while learning to attain goals in a particular environment. Eventually, the habit system becomes capable of performing a sequence autonomously without goal input. In addition to guiding learning in the habit system, the goal network enables top-down control over habitual action sequences, as when a person deliberately overrides a habitual response.

Taatgen et al. (2008) developed a model within the ACT-R (adaptive control of thought–rational) cognitive architecture that shows how behavioral control shifts from an internal, declarative task representation to environmental cues when acquiring a new action routine. Initially, explicit task knowledge is used to control behavior in a goal-directed manner. With practice, explicit memory retrieval is gradually transformed into a process by which perceptual cues trigger the relevant action directly. This proceduralization of explicit knowledge accounts for performance improvements during skill learning. Additional learning is possible by combining stimulus-cued productions of sequences into a single new production. The creation of new, specialized knowledge structures or chunks that can be used more efficiently is a central element in cognitive theories of skill acquisition (Newell 1990).

In cognitive neuroscience, the prevalent theoretical perspective is that goal-directed actions and habits can be described by different classes of RL (Daw et al. 2005, Dolan & Dayan 2013). Goal-directed, or model-based, learning is a computationally demanding process of mental simulation and planning. Using this approach, an agent computes on the fly which action maximizes long-run cumulative reward. Habit formation, in contrast, relies on model-free RL involving trial-and-error learning to estimate and store the long-run values of actions that are available in the different states or contexts. Actions are then chosen based on the stored or cached action values, reflecting predictions about future reward. Model-free control lacks the flexibility of model-based learning because short-term changes in the reward value of an action outcome have only limited effect on the cached value. Thus, model-free RL theoretically captures a key property of habits—insensitivity to changes in reward. Both types of learning are driven by prediction errors, with model-based learning capturing the discrepancy between the current state and the expected one and model-free learning capturing the difference between predicted and experienced reward.

In an initial dual-system RL model, Daw et al. (2005) assumed a competitive, winner-take-all mechanism in which the habit system or the goal system gained control over action, depending on which system provided the more reliable estimates of action values. However, subsequent investigations favor a more dynamic integration in which both systems contribute to the computation of action values according to their relative reliabilities (Lee et al. 2014). A related proposal involves Bayesian model averaging that takes into account prediction accuracy and model complexity. In this view, with experience, goal-directed actions are replaced by habits because the habit system becomes increasingly reliable and favored over the computationally more complex goal-directed system (FitzGerald et al. 2014). Furthermore, is it likely that model-based judgments are implemented only selectively, given the psychological costs of planning (see Habit and Deliberation section)? In recognition, a number of contingent RL systems engage model-based processing conditional on trade-offs between accuracy and efficiency (Keramati et al. 2011, Pezzulo et al. 2013).

Beyond integrating independently computed action values, some RL models assume a direct influence of goal values on habit learning. For example, in Gershman et al.'s (2014) two-step decision task, participants changed their choice preferences in the first task step after independently learning about second-step reward contingencies. To account for this finding, Gershman and colleagues argued that the model-based system simulated a complete two-step decision process, and

REVIEWS IN ADVANCE

Changes may still occur before final publication online and in print

the model-free system learned from the simulations. Similarly, Pezzulo et al. (2013) proposed that model-based planning can update and improve the value estimates of the model-free system. By enabling goals to influence the action values represented in habit learning, these models promote the formation of habits compatible with goals.

The RL approach can account not only for the insensitivity of habits to changes in reward value but also for the chunking feature of habit automaticity. Theories of hierarchical RL show that it can be advantageous to concatenate individual actions and treat the sequence as a single response unit or chunk (Botvinick & Weinstein 2014) because the faster responding enabled by chunking can lead to greater average reward (Keramati et al. 2011). The chunked units could be deployed in a goal-directed (Dezfouli & Balleine 2012) or model-free manner on the basis of the reward history (Botvinick et al. 2009).

Questions remain, however, about the appropriateness of equating model-free learning with habit processes. Dezfouli & Balleine's (2012) proposal that habits are action chunks that are acquired and controlled through model-based processes marks a radical departure from the common RL assumption that habits are the result of model-free learning. Even more significant, individual-difference studies have reported that the strength of model-free learning was unrelated to habit formation and insensitivity to the value of the task outcome (Friedel et al. 2014, Gillan et al. 2015). Instead, outcome insensitivity was greater among participants evidencing little model-based learning. It is possible that the standard two-stage RL decision task does not capture the process that produces outcome-insensitive habits, perhaps because participants have to choose between multiple outcomes with varying reward rates (see discussion in the Associative and Reward Mechanisms in Habit Learning section). Thus, model-free learning in these tasks might reflect other stimulus-driven strategies such as simple decision heuristics instead of habits. Future research on model-free processes may need to develop new experimental tasks to better capture habits.

In summary, habits form as a product of repeated behaviors in the service of goal pursuit. Learning in the habit system may proceed independently or be guided by the goal system. Recent theories suggest that rather than being independent action controllers, habit and goal systems integrate in ways that reflect the reliability of each system and the costs of planning. In some contingent RL models, the habit system serves as an efficient default, and people plan only when motivated and able.

NEUROBIOLOGY OF HABITS

From a dual-system perspective, a fundamental objective is to identify brain regions whose activity is uniquely associated with habitual and goal-directed behavior, respectively. Current neuroscientific research is guided, to an increasing extent, by the computational RL models that we discussed in the previous section. Thanks to the rapid advancement of functional neuroimaging with human subjects, it is now possible to relate computational dual-process models to brain functioning at increasingly fine-grained levels of analysis. The emerging picture is one of a neurocognitive system that integrates the computations of partially overlapping neural systems of habitual and goal-directed control.

Neural Systems Associated with Habits

Research conducted with rodents, monkeys, and humans has provided converging evidence that habitual and goal-directed behaviors are mediated by neural circuits that link cortical brain areas and the basal ganglia (BG), a collection of subcortical nuclei. These circuits are organized as anatomically separate reentrant loops, two of which are essential for deliberate and habitual responding (Burton et al. 2015, Yin & Knowlton 2006). The associative cortico-BG loop supports

working memory functions and goal-directed actions and links the prefrontal cortex (PFC) with two striatal BG regions, the caudate nucleus and the anterior putamen. The sensorimotor loop underlies automatic, habitual behaviors and connects the somatosensory and motor cortex with the medial and posterior putamen. Though anatomically separate, the two loops can interact, for example, through spiraling dopaminergic connectivity (Haber et al. 2000).

Animal learning studies have demonstrated the importance of the sensorimotor loop for habitual responding. Rats do not acquire a lever-pressing habit when their dorsolateral striatum (DLS), the equivalent of the primate putamen, is lesioned prior to lever-press training for sucrose. Even after extended training, these rats continued to be goal directed and pressed the lever less frequently when sucrose was devalued (Yin et al. 2004). Furthermore, when the DLS was inactivated pharmacologically after a lever-pressing habit was acquired, outcome sensitivity was reinstated (Yin et al. 2006).

Suggesting that the DLS is involved in the chunking of individual actions into a sequence, electrical recordings from neurons in the DLS of rats exhibited a task-bracketing pattern of activity during habitual runs through a maze—high neuronal activity at the beginning and end of a run, with lower activity in-between. Task bracketing emerged when the learned behavior was still goal directed (Smith & Graybiel 2013), which indicates that habits develop in parallel with goal-directed learning but do not influence overt behavior early in training. By contrast, when goal-directed control is abolished by lesioning associated brain regions such as the rodent posterior dorsomedial striatum (DMS, corresponding to the caudate nucleus in primates) or the prelimbic medial PFC, behavior immediately comes under habitual control (Killcross & Coutureau 2003, Yin et al. 2005).

Neuroimaging research with human participants implicates similar networks of brain regions. Practicing sequences of finger movements for days or weeks decreased brain activation in areas associated with goal-directed control [e.g., premotor and prefrontal cortical areas, anterior cingulate cortex (ACC), and associative BG territories] and increased activation in the sensorimotor network, including the putamen (e.g., Lehéricy et al. 2005, Steele & Penhune 2010). Participants who developed a lever-pressing habit for potato chips and candy over three days of training showed similar increases in activity in the sensorimotor striatum (posterior putamen) both within practice days as well as across days (Tricomi et al. 2009). Neuroimaging studies of motor sequence learning further confirmed the role of the sensorimotor striatum in chunk formation, along with a frontoparietal network and the mediotemporal lobes (Lungu et al. 2014).

The sensorimotor loop is critical for habit learning, and an extended network of brain regions modulates its activity. Motivational influences on habit acquisition are mediated by ascending dopamine projections from the substantia nigra pars compacta to the dorsal striatum that modulate habit plasticity at corticostriatal synapses (Balleine & O'Doherty 2010). Lesioning this nigrostriatal pathway in rats disrupted habit formation (Faure et al. 2005). Habit acquisition also was impeded by lesions of the amygdala central nucleus, most likely due to its effect on substantia nigra pars compacta function (Lingawi & Balleine 2012). Finally, rodents' infralimbic cortex, a medial PFC region, directly participates in the formation of a habit and is required for its expression (Killcross & Coutureau 2003, Smith & Graybiel 2013).

Whether the sensorimotor loop is responsible for long-term habit storage remains unclear. After six months of practicing sequences of joystick movements, monkeys that had their sensorimotor loop disrupted pharmacologically were not impaired in the expression of sequence knowledge and still executed overlearned sequences faster and more accurately than random control sequences (Desmurget & Turner 2010). One explanation is that, with extensive practice, habit learning is consolidated in cortical brain areas (Atallah et al. 2007). This possibility fits Penhune & Steele's (2012) conclusion that long-term representations of learned skills are encoded in a network of

REVIEWS IN ADVANCE

Changes may still occur before final publication online and in print

motor cortical regions. In their research, delayed recall of a motor sequence engaged not the BG but rather cortical regions (primary motor and premotor cortices and parietal lobe). This idea is supported further by the finding that participants who practiced motor sequences for more than six weeks showed, late in training, neural specialization in cortical motor areas [primary motor and premotor cortices and the supplementary motor area (SMA)] (Wymbs & Grafton 2014).

In summary, converging evidence implicates the sensorimotor cortico-BG loop as the core neural substrate of habit learning and performance. Whether the BG is also required for the long-term retention of habits is a matter of current debate.

Neural Systems that Integrate Habit and Goal-Directed Action Control

Based on computational RL theory, a stream of neuroimaging research has evaluated performance in sequential decision tasks that elicit both habit-based (model-free) learning and prospective planning about outcomes (model based). The results are broadly consistent with the mapping of habitual and goal-directed control onto the associative and sensorimotor cortico-BG loops. For example, Wunderlich et al. (2012) related activity in the posterior putamen to cached action values (habits) that were acquired through extensive training, and activity in the anterior caudate nucleus was related to values used in model-based planning. Similarly, Lee et al. (2014) reported that the posterior putamen, SMA, dorsomedial PFC, and dorsolateral PFC encoded model-free action values, whereas model-based values were associated with activity in orbitofrontal cortex (OFC) and medial PFC as well as the ACC (see also de Wit et al. 2009, Valentin et al. 2007).

Recent dual-system RL models propose that response selection is based on action values represented in ventromedial prefrontal cortex (vmPFC) that are jointly determined by a model-free (habit) and prospective planning controllers (e.g., Daw et al. 2011). This integration of model-based and model-free value signals is thought to be conducted by an arbitrator associated with activity in the inferior lateral PFC, frontopolar cortex, and ACC (Lee et al. 2014). How exactly such an arbitrator regulates the contribution of each system is still largely unknown. According to one analysis, shifts in response strategy are achieved primarily by strengthening or inhibiting the influence of the model-free habit system (Lee et al. 2014). Other findings suggest dynamic changes in both the habit system and the goal system (Gremel & Costa 2013).

Consistent with the idea that habits develop as people pursue goals, recent evidence suggests that multiple brain regions participate in both goal-directed and habitual control. For example, Lee et al. (2014) found with the multi-step decision task that two regions, the SMA and dmPFC, represented both model-free and model-based values. Similarly, Gremel & Costa (2013) trained rats to lever press for sucrose using either a habitual or a goal-directed strategy. They reported that a large proportion of neurons in DLS, DMS, and OFC participated in both habitual and goal-directed responding, and that the relative engagement of neurons in these areas depended on the current response strategy.

In summary, research guided by RL theory has identified the neural substrates of model-based (goal-directed) and model-free (habitual) control. These neural systems are partially overlapping, and their computations are integrated by brain regions that regulate the relative influence of the two modes of behavioral control.

FACTORS THAT SHIFT THE BALANCE BETWEEN HABITS AND DELIBERATE GOAL PURSUIT

Given the cognitive and neural features that differentiate habitual responding from more deliberate pursuit of goals, action control proceeds by balancing these and other processes (e.g., Pavlovian

HABIT SLIPS

Habit slips, or errors of inadvertent habit performance, occur primarily when an intended action and a habit share a performance context or some action component (Norman 1981). In daily life, people appear to slip up by performing unwanted habits about six times a week, especially when their attention is diverted from the task at hand (Reason 1979). For example, habit slips underlie errors in responding to innocent-appearing email phishing attacks (Vishwanath 2015). In laboratory tests, habits were most likely to be performed inadvertently when goal-directed control was taxed by, for example, advanced age or performing a secondary task (e.g., de Wit et al. 2014, Ruh et al. 2010).

Moving beyond the truism that people make errors when not attending to what they are doing, research has identified several sources of habit slips. Slips arising from failures in planning reflect limits in motivation or knowledge about completion of task goals, and they are most likely at decision points such as the end-of-task subroutines (Norman 1981, Reason 1979). However, habit slips also emerge from failures in automated, habitual guides to performance, as when degraded or forgotten representations of task context occur within a sequence of well-learned actions (Botvinick & Bylsma 2005). In still another analysis, habit slips arise from normal processing, especially open-loop action control in which habits are executed ballistically once they are launched, even when they are not the optimal response (Dezfouli et al. 2014, Orbell & Verplanken 2010). Thus, habit slips reflect failures to select the correct action through top-down control or bottom-up activation as well as ballistic habit performance.

Annu. Rev. Psychol. 2016.67. Downloaded from www.annualreviews.org
Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

conditioning; de Wit & Dickinson 2009). Tipping the balance between habits and goal pursuit are factors such as distraction (see Habit Slips sidebar), time pressure, limited task ability, or limited willpower (for a review, see Wood et al. 2014). These factors drive action control by pitting efficiency in processing against more effortful reliable processing (Evans & Stanovich 2013). That is, people act on strong habits when they lack the ability and motivation to engage the central executive in deliberation or, in RL terminology, when pressured by the time costs of model-based planning.

Considerable research reveals increased habit performance with impaired executive functioning. For example, when willpower was reduced by previously performing a taxing decision-making task, participants did not tailor their responses to their current circumstances but instead fell back on strongly habitual choices (Neal et al. 2013, Vohs et al. 2005). Also, when distracted by performing a demanding task, participants completing a categorization task increased the use of stimulus-response strategies over rule-based ones (Foerde et al. 2006), and participants completing a multistep decision task increased model-free responding (Otto et al. 2013a). Furthermore, in individual-difference paradigms, older adults and those with lower cognitive-control abilities were less able to leverage higher-order goal representations for model-based responding in order to overcome habitual, model-free solutions to a variety of tasks (de Wit et al. 2014, Otto et al. 2015). In like manner, participants possessing low spatial perspective-taking ability, after practicing navigating a maze, used more habitual and less goal-directed navigation strategies (Marchette et al. 2011).

Stress and drug addiction are of particular interest because of the multiple routes by which they tip the balance toward habits and away from deliberate decision making. As we explain in the next sections, these factors not only impede executive processes but also perhaps promote habit learning.

Stress

Acute as well as chronic stress can increase people's reliance on habits (Schwabe & Wolf 2013). For example, participants exposed to a combination of physical and psychosocial stressors (immersing a

REVIEWS IN ADVANCE

Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

hand into ice water while being monitored by a stranger and videotaped) after instrumental learning acted more habitually and were less sensitive to changes in the value of task rewards (Schwabe & Wolf 2010). This stress-induced shift toward habits is due in part to stress impeding deliberate action control. At the neural level, the shift toward habitual behavior was accompanied by decreased activity in OFC and medial PFC, brain regions associated with goal-directed learning (Schwabe et al. 2012). In sequential decision-making tasks, acute stress selectively attenuated deliberate, model-based control and promoted habit performance in vulnerable participants—those with low working-memory capacity (Otto et al. 2013b) or high levels of chronic stress (Radenbach et al. 2015). Similarly, in a study of visual classification learning, stressed participants were biased toward relying on a habit-linked procedural learning strategy at the expense of explicit learning (Schwabe & Wolf 2012). These results could reflect simply the breakdown of higher-order decision-making functions under stress, or stress could lead to a shift in the allocation of cognitive resources so that people fall back on habits and other strategies to prevent unreliable performance. From an RL perspective, stress shifts the balance toward habits over lengthy planning by increasing experienced time pressure (Doll et al. 2012).

Along with impeding deliberate thought, stress also might promote habit acquisition. Research with rodents suggests that stress can, under specific conditions, facilitate habit learning through mechanisms associated with dorsolateral striatal function (Dias-Ferreira et al. 2009). In humans, however, stress does not clearly affect habit formation. To isolate stress effects on habit learning, stress is induced before training, and learning is assessed after acute stress effects have dissipated so that these do not affect performance. Administering stress hormones led to improved learning in a simple stimulus-response task but had no effect on habit learning in a virtual radial maze (Guenzel et al. 2014a). Furthermore, a combination of pretraining physical and psychosocial stressors actually impaired habitual performance at maze navigation, albeit only in male participants (Guenzel et al. 2014b).

In summary, neurophysiological responses to stress increase habitual responding by impeding deliberate action control and, potentially, by promoting habit formation. More generally, stress research highlights the benefits of habits for rescuing performance. In support of this functional role, stressed participants' task performance was impaired to the extent that they attempted to engage goal-directed neural systems (Schwabe & Wolf 2013). Given the ready acquisition and performance of habits, they provide a useful default when threat and pressure derail more thoughtful responding.

Addiction

From a habit perspective, the path to drug addiction involves not a pathological motivation for drugs but rather a shift from goal-directed to habitual drug seeking and consumption (Everitt 2014, Hogarth et al. 2013). Initial drug seeking is voluntary and reflects the hedonic value of the drug. Through instrumental learning with drug rewards, context cues rapidly become associated with drug use. In addition, Pavlovian mechanisms contribute to the want for drugs and for cue-evoked cravings (Berridge 2007). These various learning mechanisms are involved in the cues that come to trigger drug seeking and consumption independently of the drug outcome, much as people repeat habits with limited sensitivity to goals and outcomes (Zapata et al. 2010). Phenomenologically, the addict no longer likes the drug yet uses it compulsively, often despite intentions to quit. Drug-outcome insensitivity is promoted further as repeated exposures build tolerance to rewarding drug effects.

Drug use promotes habit formation in part by impairing goal-directed control. In illustration, study participants who had consumed alcohol responded habitually and continued to choose

REVIEWS IN ADVANCE

chocolate in a repeated food-choice task despite having just eaten three chocolate bars (Hogarth et al. 2012a). Comparable findings have emerged with chronic addicts abstinent at test. For example, participants who were obese, obsessive-compulsive, or dependent on methamphetamine (abstinent at test) showed compromised goal-directed learning at a decision-making task, along with a maladaptive reliance on habits (Voon et al. 2015). Furthermore, these responses in chronic addicts were associated with neural markers of lower gray matter volumes in the caudate, medial OFC, and lateral PFC. Also, alcohol-dependent participants responded habitually after rewards had been devalued in an associative learning task, and greater reliance on habits was associated with reduced engagement of brain areas implicated in goal-directed action (vmPFC) and increased engagement of areas implicated in habit learning (posterior putamen; Sjoerds et al. 2013). Even when not under drug influence, simply being in the presence of cues repeatedly associated with drug exposure can disrupt goal-directed responding (Ostlund et al. 2010). In general, goal-directed impairments increasingly narrow addicts' behavioral repertoires onto drug habits by restricting their capacity for intentionally selecting alternative actions.

Drug use also promotes habit responding through neurobiological processes that sensitize users to the incentive properties of drugs. Drug rewards appear to engage habits more rapidly than other reinforcers (see review in Everitt 2014). Stimulants in particular accelerate and consolidate the development of drug use habits, speeding the neural shifts from associative to sensorimotor areas typically found with habit formation. The accelerated formation of habits hastens the transition from initial or occasional user to addict.

In summary, drug exposure hijacks the habit learning system by exerting a continuous pressure in favor of habitual, context-driven behavior and away from the evaluation of the outcomes of action. As a result of these habitual and deliberative processes, drug use escalates so that people ultimately seek drugs compulsively (Redish et al. 2008).

INFERENCES ABOUT THE CAUSES OF HABIT PERFORMANCE

People often are aware of their habitual responses although they are largely unaware of the cuing mechanism that activates habits. Given this limited introspective access, people's explanations for their habitual responses are largely post hoc accounts. According to classic social psychology theories, when internal cues to action are weak, ambiguous, or uninterpretable, people infer what their motivations must be from observing their behavior and the context in which it occurs (Bem 1972).

The simple frequency of habit performance plausibly implies strong, consistent underlying motives. Such inferences could be correct in an historical sense, because people might accurately remember the goals that initially guided habit formation. However, they will not be correct concerning current habit performance. In support of such an inference, participants with stronger habits were more certain about their behavioral intentions and perceived the behavior as guided more by their goals than were participants with weaker habits, when in fact the opposite was true—intentions and goals were particularly poor predictors of strongly habitual behaviors (Ji & Wood 2007, Neal et al. 2012). People infer that goals underlie a range of habitual behaviors, even habits of compulsive drug seeking and use. Everitt & Robbins (2005) suggested that addicts' experience of wanting a drug is not a precursor of consumption but rather a post hoc rationalization of compulsive drug-use habits. Similarly, obsessive-compulsive disorders may originate in excessive habit formation, with irrational threat beliefs then inferred to explain the compulsively repeated behaviors (Gillan & Robbins 2014). Although people infer intentionality for a wide variety of automatically cued responses, when internal cues are strong and unambiguous, causal inferences

REVIEWS IN ADVANCE

Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

are unnecessary. Then, inconsistencies between habits and goals might just be labeled as such (e.g., "I can't help it, it's a habit").

The inference of motives behind habit performance is represented in some computational models as non-goal-mediated routine responding giving rise to goal representations. For example, in Sun et al.'s (2001) CLARION (Connectionist Learning with Adaptive Rule Induction Online) model, habitual responses that are controlled through bottom-up procedural knowledge can, over time, come to be represented in top-down rules via a rule extraction-refinement algorithm. In Cooper et al.'s (2014) goal circuit model, stimulus-driven habitual responses can activate goal representations that subsequently provide input to habits. In this way, active goals may be a consequence, rather than a precursor, of habitual action. From the perspective of RL models, this inference might occur through the model-based system adopting the values expressed in habit learning, perhaps to reduce computational overhead (Doll et al. 2012).

Goal inferences are sparked not only by the simple frequency of habit performance but also by the positive affect associated with many habits. Habits are likely to be favored due to the ease with which they can be performed compared with alternatives. Thus, consumers value using existing products and services over new ones because of the difficulty of learning new usage behaviors (e.g., computer program updates; Murray & Häubl 2007). Habits also are likely to be viewed positively due to the fluency or speed and ease of processing associated with frequently performed behaviors. High fluency is experienced as positive in part because it signals familiarity over uncertainty and success at processing and understanding, and this positive affect generalizes to evaluation of the activity (Reber et al. 2004). Habit inferences thus exploit a psychological calculus that favors what feels easy because it is well practiced over what feels more difficult because it is new. Being favorably disposed toward habits, people may infer that they intended to perform the response.

Although the inferences that follow habit performance may not be accurate descriptions of the mechanisms actually generating action, such inferences sometimes contribute to well-being. Repeated behaviors, such as students' choices of the same seat in a classroom, heighten feelings of comfort, confidence, and control despite that these choices might initially be random (Avni-Babad 2011). Furthermore, habit performance may promote coherence or comprehensibility of experiences and thus enhance meaning in life (S. Heintzelman and L. King, unpublished observation). However, inferences about habits are not always beneficial, and the transparency of habit knowledge to introspection can lead people to underestimate its usefulness. For example, when highly motivated to perform well, participants with good procedural knowledge at a task overrode their habits and responded thoughtfully, despite that this impaired task performance (L. Carden, W. Wood, D. Neal, and A. Pascoe, unpublished observation).

In summary, people may explain habit performance, even addictive habits, by inferring relevant goals and intentions. Despite being largely erroneous, the inference that habits were intended may seem intuitively plausible given response frequency. Also relevant, switching costs can discourage deviating from habits, and experienced fluency can increase liking for them.

CHANGING HABITS

Unwanted habits are at the root of many failed attempts at behavior change. Evidence comes from Webb & Sheeran's (2006) meta-analysis of 47 studies that successfully used persuasive appeals and other interventions to change participants' intentions. The changed intentions, however, only yielded change in behaviors that participants performed sporadically (e.g., course enrollment) and not in behaviors that could be repeated into habits (e.g., seat belt use). Even the largely effective implementation intentions, or if-then plans to act on intentions at particular times and places (Gollwitzer & Sheeran 2006), are not successful at controlling many strong habits (Webb et al. 2009).

REVIEWS IN ADVANCE

Changes may still occur before final publication online and in print

From a habit perspective, difficulties in changing established behavior patterns do not reflect people's continuing desire to perform the old behavior or a failure of willpower. The central challenge is that old habits continue to be activated automatically by recurring environmental cues (J. Labrecque and W. Wood, unpublished observation; Walker et al. 2014). Even after new habits have been learned, old memory traces are not necessarily replaced (Bouton et al. 2011). Relapse can occur when old habit memories are activated by prior routines and other context cues.

Addressing the role of habit learning is a central challenge for the next generation of behavior change interventions (Marteau et al. 2012, Rothman et al. 2015). In response to this challenge, interventions can be designed to (*a*) impede the automated cueing of old, unwanted habits as well as (*b*) promote the repetition of a new, desired behavior into a habit.

Annu. Rev. Psychol. 2016.67. Downloaded from www.annualreviews.org
Access provided by University of California - Santa Barbara on 09/13/15. For personal use only.

Interventions to Impede Unwanted Habit Performance

To reduce interference from old habits, behavior change interventions can incorporate mechanisms of inhibition. In research investigating the spontaneous inhibition of unwanted habits in daily life, the most successful strategy involved thinking, "Don't do it," and being mindful of slip-ups (Quinn et al. 2010). This strategy also successfully controlled habit errors when participants were instructed to use it in an experimental task. As expected, it worked by enhancing cognitive control, not by decreasing habit strength (Quinn et al. 2010). Also effective is tying inhibitory plans to the cues that activate unwanted habits (e.g., "After dinner, I'll skip dessert as usual and substitute fruit"; Adriaanse et al. 2010).

Interference from old habits also can be reduced by changing cues in performance environments. Animal research suggests that habit performance is especially impaired when contexts shift, with goal-directed responding transferring more successfully across contexts (Thrailkill & Bouton 2015). One way to change habit cues is through managing exposure. For example, unhealthy eating habits can be curbed by increasing the salience or accessibility of healthy foods (Sobal & Wansink 2007). A study illustrated how people do this in daily life: At all-you-can-eat Chinese buffets, patrons with lower body mass index used chopsticks, chose small plates, put napkins on their laps, and sat with their sides or backs to the buffet (Wansink & Payne 2012). Another way that habit cues change is through naturally occurring life transitions, such as when people switch jobs or move house. Habit discontinuity interventions capitalize on this reduced exposure to cues that trigger old habits (Thøgersen 2012, Verplanken et al. 2008, Walker et al. 2014). Life transitions that alter habit cues can provide a window of opportunity to act on new intentions without competition from old habits (Wood et al. 2005).

Interventions to Promote Formation of Desired Habits

By encouraging the formation of new habits, behavior change interventions can be designed to habitize a new behavior so that it is maintained despite short-term desires and temptations. In an experiment illustrating how healthy habits can arm people against succumbing to food temptations (P.-Y. Lin, W. Wood, and J. Monterosso, unpublished data), participants learned in a computerized task to avoid chocolate (study 1) or to choose carrots (study 2). When later given options of eating unhealthy treats, participants continued to make habitual choices, at least when context cues automatically triggered the healthy habit. Also, echoing the factors that balance habits and goals, participants were most likely to act on their healthy habits when they lacked the willpower to deliberate about food choices.

Despite the promise of habit formation in maintaining desired behaviors, only a few interventions with nonclinical populations have built on the three pillars of habit formation–repetition in

stable contexts with appropriate reward schedules (see Lally & Gardner 2013, Rünger & Wood 2015). The importance of frequent responding was illustrated in Lally et al.'s (2010) field experiment in which repetitions of a simple health behavior (e.g., walking after dinner) required from 18 days to as many as 254 days in the same context to become habitual and performed without thinking. For exercise, Kaushal & Rhodes (2015) estimated that going to the gym became automatic within six weeks, assuming visits of four times per week. Unfortunately, few health or other behavioral interventions have adapted interval reward schedules to facilitate habit formation (Burns et al. 2012). However, the importance of stable cues was demonstrated in interventions using tooth brushing to cue dental flossing and form flossing habits (e.g., Judah et al. 2013, Orbell & Verplanken 2010). The few interventions built on the three components of habit formation have yielded promising results for weight loss (Carels et al. 2014, Lally et al. 2008) and consumption of healthy food in families (Gardner et al. 2014).

Interestingly, in a habit formation intervention, electronic reminders to perform a desired behavior increased repetition but also impeded automaticity and learning of context-response associations (Stawarz et al. 2015). Perhaps reminders engaged deliberate decision making that impaired learning context–response associations (see Associative and Reward Mechanisms in Habit Learning section). More passive reminders in the form of physical signs, although helpful in prompting initial repetition and habit formation, ultimately lost potency over time (Tobias 2009).

Additional evidence of the utility of habit formation comes from interventions that did not specifically target habits. For example, forming gym-going habits enabled new members of a health club to sustain working out (Armitage 2005), and forming nonsmoking habits enabled former smokers to remain abstinent a year after the end of a smoking cessation program (Baldwin et al. 2006). In a study of regular exercisers, approximately 90% had a location or time cue to exercise, and exercising was more automatic for those who exercised in a routine way and were cued by a particular location (Tappe et al. 2013).

Research on self-control also suggests the usefulness of habits for maintaining desired behaviors. People with high trait self-control do not appear to attain goals through inhibition of problematic desires but instead through forming habits that allow them to achieve goals without experiencing unwanted temptations (Galla & Duckworth 2015, Hofmann et al. 2012). Trait self-control generally fosters proficiency at performing tasks that require automation (de Ridder et al. 2012). Nonetheless, everyone tends to fall back on performing habits—both good and bad—when they lack the capacity or motivation to make decisions to act in nonhabitual ways (Neal et al. 2013).

In summary, through combating unwanted habits and ensuring that desired behaviors are repeated in ways that promote habit formation, interventions can promote adoption of behaviors that endure over time. These interventions adapt the habit strategies that people with effective self-control use in their daily lives to ensure successful goal attainment.

CONCLUSION

The current state of the science on habits has provided the definition that James (1890) requested, overturned behaviorists' conceptions of simple stimulus-response associations, and placed habits within broader models of goal-directed action. Habits reflect associative learning and the formation of context-response associations in procedural memory. Once habits form, perception of the context automatically brings the response to mind, and people often carry out that response. As habits strengthen, they gradually become independent of the incentive value of their consequences, and neural activation shifts from associative toward sensorimotor cortico-striatal brain regions. When repeated in a sequence, habitual responses also may be chunked together and activated as a unit. In short, our review provides a framework for understanding, predicting, and changing that

common component of everyday life in which behavioral control has been outsourced onto the context cues contiguous with past performance.

Although habits are largely insensitive to changes in goal structure and value, they interact in three different ways with deliberate goal pursuit. First, habits form in daily life as people pursue goals by repeating actions in particular performance contexts. Initially, goals and declarative task knowledge structure behavior. With repetition, responses and associated context cues are captured in procedural learning systems. Goals also may contribute to habit formation through heightening attention to certain stimuli and identifying the value of action outcomes. Given the profusion of direct and indirect connections between neural circuits underlying goal-directed and habitual (model-free) behaviors, goals can have a biasing influence on habit formation (Doll et al. 2012). Cross talk between habit systems and more deliberative action control, especially during habit formation, is consistent with an evolutionary history in which neural systems supporting more sophisticated planning capacities evolved on top of neural mechanisms associated with habits.

A second interface between goals and habits emerges after habits form. That is, habits provide an efficient baseline response that likely integrates with more effortful goal pursuit only when necessary, as when habits prove unreliable in a given context or when people are especially motivated and able to tailor responses to particular circumstances. Various factors impede people's ability to deliberate and thus tip the balance toward relying on habits, including time pressure, distraction, stress, and addiction. Addictive substances may in addition promote habit responding by accelerating habit learning.

A third way in which goals integrate with habits is through the explanations that people generate for their habits. Because habit automaticity is inaccessible to subjective experience, people must infer the reasons for such responses. A plausible inference for repeated behaviors is strong, consistent underlying motivations and goals.

The research we reviewed highlights a number of advantages to acting habitually. For example, habit knowledge is protected from short-term whims and occasional happenings, given that habits form through incremental experience and do not shift readily with changes in people's goals and plans. Also, by outsourcing action control to environmental cues, people have a ready response when distraction, time pressure, lowered willpower, and stress reduce the capacity to deliberate about action and tailor responses to current environments. Furthermore, habit systems are smart in the sense that they enable people to efficiently capitalize on environmental regularities.

As we noted at the end of the present review, understanding habits is important from the applied perspective of human health and welfare. Drug addictions and other compulsions appear to co-opt habit processes and reduce people's capacity to purposively guide their behavior. Lifestyle habits of poor diet and limited exercise are major contributors to chronic diseases. By building on an understanding of habit mechanisms, addiction treatments as well as interventions to change lifestyle behaviors may successfully disrupt these unwanted habits and help people to form more effective habits that meet their goals for healthy, productive lives.

Responses of Monkey Dopamine Neurons to Reward and Conditioned Stimuli during Successive Steps of Learning a Delayed Response Task

Wolfram Schultz, Paul Apicella,[a] and Tomas Ljungberg[b]

Institut de Physiologie, Université de Fribourg, CH-1700 Fribourg, Switzerland

The present investigation had two aims: (1) to study responses of dopamine neurons to stimuli with attentional and motivational significance during several steps of learning a behavioral task, and (2) to study the activity of dopamine neurons during the performance of cognitive tasks known to be impaired after lesions of these neurons. Monkeys that had previously learned a simple reaction time task were trained to perform a spatial delayed response task via two intermediate tasks. During the learning of each new task, a total of 25% of 76 dopamine neurons showed phasic responses to the delivery of primary liquid reward, whereas only 9% of 163 neurons responded to this event once task performance was established. This produced an average population response during but not after learning of each task. Reward responses during learning were significantly more numerous and pronounced in area A10, as compared to areas A8 and A9. Dopamine neurons also showed phasic responses to the two conditioned stimuli. These were the instruction cue, which was the first stimulus in each trial and indicated the target of the upcoming arm movement (58% of 76 neurons during and 44% of 163 neurons after learning), and the trigger stimulus, which was a conditioned incentive stimulus predicting reward and eliciting a saccadic eye movement and an arm reaching movement (38% of neurons during and 40% after learning). None of the dopamine neurons showed sustained activity in the delay between the instruction and trigger stimuli that would resemble the activity of neurons in dopamine terminal areas, such as the striatum and frontal cortex. Thus, dopamine neurons respond phasically to alerting external stimuli with behavioral significance whose detection is crucial for learning and performing delayed response tasks. The lack of sustained activity suggests that dopamine neurons do not encode representational processes, such as working memory, expectation of external stimuli or reward, or preparation of movement. Rather, dopamine neurons are involved with transient changes of impulse activity in basic attentional and motivational processes underlying learning and cognitive behavior.

[Key words: behavior, motivation, learning, conditioning, reward, cognition, attention]

In previous neurophysiological studies in behaving monkeys, it was found that dopamine (DA) neurons respond to primary food and fluid rewards and to conditioned incentive stimuli predicting reward (Schultz, 1986; Romo and Schultz, 1990; Ljungberg et al., 1992). Responses to conditioned stimuli have also been observed in awake, haloperidol-treated rats (Miller et al., 1981). DA neurons also respond to novel, unexpected stimuli, both in cats (Steinfels et al., 1983) and in monkeys (Ljungberg et al., 1992). These data suggest that DA neurons respond to salient environmental stimuli that alert the animal and attract its attention. Large, albeit not exclusive, classes of these effective stimuli are primary and learned appetitive motivating stimuli.

Primary rewards, novel stimuli, and conditioned incentive stimuli play particularly prominent roles when an animal learns new or changed behavioral contingencies for obtaining reward. We have investigated the responses of DA neurons to various stimuli while animals learned simple reaction time tasks (Ljungberg et al., 1992). It was found that neurons responded to the sight or reception of primary reward during learning, and that these responses were transferred to the conditioned stimulus predicting reward when task performance was established. These responses to the conditioned stimulus were strongly reduced after overtraining. These data suggest that the responses of DA neurons may be particularly important during learning when the animal adapts its behavior to new situations.

The present study aimed to answer two questions. (1) If the responses of DA neurons are transferred between the most significant stimuli during the course of learning, then how would these neurons respond when the learning of a more elaborate task requires a consecutive series of intermediate subtasks and does not occur in basically a single step, as with a reaction time task? More complicated tasks performed by monkeys in a laboratory setting could comprise the choice of different spatial targets for the behavioral response and involve working memory and the preparation of movement. (2) It would be particularly interesting to see how the activity of DA neurons changes during the performance of such tasks, since Parkinsonian patients and animals with lesions of DA neurons show considerable difficulties in performing tasks requiring the use of declarative cognitive or procedural representations (Brozoski et al., 1979; Simon et al., 1980; Cools et al., 1984; Saint-Cyr et al., 1988; Schneider and Kovelowski, 1990). In combining these two questions, we

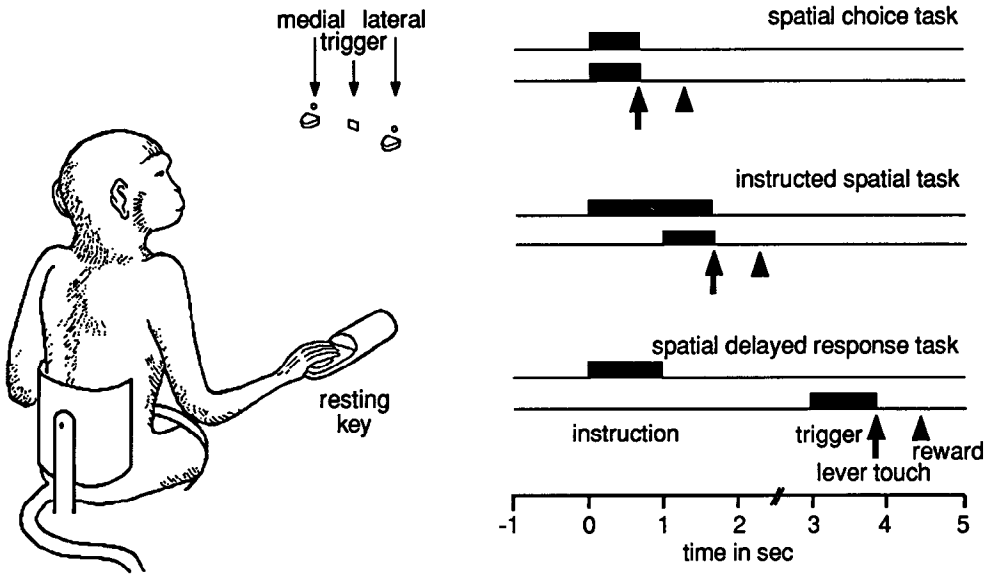

Figure 1. Schematic description of behavioral tasks. A trial is initiated when the animal keeps its hand relaxed on the immovable resting key. Illumination of an instruction light above the medial or lateral lever indicates the future target of reaching. The trigger light determines the time when the resting key should be released and the lever indicated by the instruction touched. Medial and lateral levers are used in random alternation. In the spatial choice task, both instruction and trigger lights come up at the same time and are extinguished upon lever touch. In the instructed spatial task, the trigger light comes up 1 sec after the instruction, and both lights are extinguished upon lever touch. In the spatial delayed response task, the trigger comes up after a randomly varying interval of 2.5–3.5 sec after instruction onset. The instruction is extinguished 1 sec after it came up. Thus, the animal cannot precisely predict when the trigger light comes up and needs to retain the spatial position of the lever until it is allowed to move in response to the trigger. Reward is given in all tasks 0.5 sec after correct lever touch.

studied DA neurons while monkeys learned in several steps a spatial delayed response task in which they needed to remember the spatial position of a cue for several seconds, prepared for an upcoming arm movement, and executed it when a trigger stimulus came up. Because we only wanted the animals to advance in learning the tasks while we recorded from a DA neuron, task acquisition was facilitated by using animals that had already learned a simple reaction time task (Ljungberg et al., 1992), and by employing the most basic version of a delayed response task with only two reaching targets that were constantly visible to the animals.

These data have been presented previously in short form (Schultz et al., 1991).

Materials and Methods

The study was performed on two male *Macaca fascicularis* monkeys of 3.5 kg weight. Activity of single neurons was recorded with moveable microelectrodes during learning and established performance of three consecutive spatial reaching tasks. Animals were killed for histological reconstruction of recording sites. A third monkey was used before the recording experiments for the development of task learning. The behavioral apparatus and recording techniques were similar to those previously reported (Schultz, 1986; Ljungberg et al., 1992).

Behavioral procedures

The behavioral apparatus was positioned at reaching distance (250 mm from the animal's shoulder) in the right half of the frontal wall of a completely enclosed primate chair (Fig. 1). A yellow, rectangular light-emitting diode (11 × 11 mm) was mounted at 27° lateral to the midsagittal plane and at eye level of the animal. Two small levers (7 × 15 mm) were placed 40 mm medial and lateral to the yellow light. Levers protruded by 20 mm from the frontal wall and made electrical contact upon downward movement of 1 mm. One green, round light-emitting diode of 3 mm diameter was located 10 mm above each lever. An immovable, touch-sensitive key was mounted below the lights at waist level such that the elbow joint of the animal was kept at approximately 90° when its hand rested on the key. A drop of apple juice (0.15–0.20 ml) served as reward, which was delivered by an electronically controlled solenoid valve. The solenoid emitted an audible click upon complete opening at 18 msec after the electronic pulse. Liquid arrived at the spout in front of the animal's mouth with an average delay of 55 msec after the electronic pulse. Two closed-circuit video systems served to supervise limb and mouth movements continuously. Monkeys were deprived of fluid during weekdays. They were released into their home cages after each daily experiment of 3–4 hr and received water ad libitum during the subsequent 1 hr.

Both animals had been conditioned to perform in a simple reaction time task (Ljungberg et al., 1992) in which they kept their one hand relaxed on the resting key until the yellow light came on as trigger stimulus. The animal released the key in response to this stimulus, reached out, and depressed the small lever below the light for liquid reward. In the present tasks, a spatial component of reaching was introduced by using two target levers instead of one. The correct lever was indicated by the instruction light shown at different times in the three tasks.

Spatial choice task. The instruction light situated above one of the levers came up at the same time as the central trigger light. The animal released the key in response to the two simultaneous lights, reached out, and depressed the lever indicated by the instruction light in order to receive the reward. Both lights were extinguished upon lever touch or, if no movement occurred, after 1 sec. Liquid reward was delivered 500 msec after correct lever touch. This delay allowed the separation of neuronal responses to lever touch from those to reward. Trials lasted 6–9 sec; intertrial intervals varied between 3 and 5 sec. The use of the lateral and medial levers alternated randomly between trials, but the successive use of the same lever was limited to maximal three trials.

Instructed spatial task. The instruction light situated above one of the levers came up at a fixed interval of 1 sec before the central trigger light. The animal released the resting key and touched the lever in response to the trigger light. Thus, the instruction light indicated the lever to be touched and served as preparatory signal for the upcoming behavioral response, whereas the trigger light determined the time of responding without providing spatial information. Both lights were extinguished upon lever touch or, if no movement occurred, after 1 sec. Reward was delivered 500 msec after correct lever touch.

Spatial delayed response task. The instruction light indicating the lever to be touched came up for a fixed duration of 1 sec. The central light triggering the reaching movement was illuminated at a randomly varied interval of 2.5–3.5 sec after instruction onset and was extinguished upon

lever touch or, if no movement occurred, after 1 sec. Reward was delivered 500 msec after touch of the correct lever. This situation constitutes a spatial delayed response task in which the animal has to remember the lever to be touched.

Learning of tasks. The animals, previously trained in the simple reaction time task, were first conditioned to perform the spatial choice task. After reaching stable performance for about 1 week, the task was abandoned and the instructed spatial task was introduced. After stable performance for about 1 week, this task was in turn abandoned for the spatial delayed response task. During conditioning in the spatial choice and the instructed spatial tasks, the new contingencies were introduced in one step and animals had to find the correct solution to the new problem by their own trial and error attempts. Learning of the spatial delayed response task involved a stepwise approach to the longer interval and delay. For monkey A, intervals between onsets of instruction and trigger stimuli were gradually prolonged to 3 sec, and the duration of the instruction cue was subsequently shortened to 1 sec, thus introducing the delay. For monkey B, the duration of the instruction cue was kept at 1 sec, and intervals between instruction and trigger stimuli were gradually prolonged. The acceptable interval for lever pressing after the trigger stimulus was initially set to 3 sec and gradually shortened to the final 1 sec.

Learning of each task was best described by the frequency of correct responses. Systematic changes in arm reaction time and movement time were not observed during learning, possibly because of extensive training in the previous reaction time task involving a comparable arm movement. Thus, each task was divided into the learning and the established performance parts according to the time when a stable frequency of correct responses was reached.

Data acquisition

All behavioral performance was controlled by a suitably interfaced laboratory computer, the selection of appropriate task parameters being done by the experimenters individually for each block of trials. The different lights and the solenoid for reward delivery were driven by output pulses from the computer. Key release was detected by a frequency-sensing circuit that reacted to a change in electrical capacity induced by the touch of the animal's hand. Errors in behavioral performance led either to cancellation of all further signals in a given trial, including reward, or to immediate trial restart.

Animals had been implanted for the preceding study on reaction time tasks. Under deep sodium pentobarbital anesthesia and aseptic conditions, cylinders for head fixation and a stereotaxically positioned, stainless steel chamber were fixed to the skull to permit vertical access with microelectrodes to the left substantia nigra. The dura was left intact. Teflon-coated, multistranded, stainless steel wires were implanted into the extensor digitorum communis and biceps muscles of the arm and led subcutaneously to the head. Ag-AgCl electrodes were implanted into the outer, upper, and lower canthi of the orbits. All metal components, including connector plugs for the muscle and periorbital electrodes, were embedded in several layers of dental cement and fixed to the skull with surgical grade stainless steel screws. One week after implantation, animals were anesthetized with pentobarbital and the area of substantia nigra was localized by taking lateral and coronal radiographs with a guide cannula installed at a known coordinate in reference to the implanted steel chamber. The ventroposteromedial thalamus overlying the lateral substantia nigra was electrophysiologically explored for trigeminal input on the same occasion, and later occasionally in the waking animal.

The activity of single neurons was recorded extracellularly with glass-insulated, platinum-plated tungsten microelectrodes (exposed tips of 9–16 μm length and 2.5–3.5 μm diameter), which were passed each day into the brain, together with and inside of a rigid guide cannula of 0.6 mm outer diameter. Microelectrodes were moved vertically in the stereotaxic plane in parallel tracks that conformed to a 1 mm grid. Signals from the microelectrode were conventionally amplified, filtered (100 Hz lower cutoff), and monitored with oscilloscopes and audiomonitors using earphones to prevent the monkeys from hearing the neuronal activity. Full waveforms of impulses from each neuron were displayed on a digital oscilloscope using the pretrigger viewing facility and subsequently stored on computer disks. Somatodendritic discharges were discriminated against those originating from fibers using earlier established criteria, in particular the very short durations of fiber impulses (0.1–0.3 msec) (Hellweg et al., 1977; Schultz and Romo, 1987). Neuronal discharges were also converted into standard digital pulses by means of an adjustable Schmitt trigger, the output of which was continuously monitored on the digital oscilloscope together with the original waveform. DA neurons were searched for in a systematic fashion. Every neuron fulfilling the criteria for being dopaminergic was tested with at least 20 trials of a given task situation and included in the study.

Electromyograms (EMGs) were collected during all neuronal recordings through the chronically implanted electrodes. EMG activity was filtered (10–250 Hz bandpass; −12 dB at 1 kHz), rectified, and displayed on conventional oscilloscopes. Rectified EMG activity was also passed through an adjustable Schmitt trigger and fed to the computer. Horizontal and vertical electrooculograms (EOGs) were collected during all neuronal recordings from the implanted periorbital electrodes. The gain of ocular electrodes and positions of the eyes were calibrated by having the animal fixate small morsels of preferred food presented at several known horizontal and vertical eccentricities while the frontal enclosure of the primate chair was kept open. Direct current offset had to be adjusted once every 3–4 weeks.

All behavior-related digital signals and pulses from neuronal discharges and EMG activity were sampled on line as bits in parallel at a rate of 2 kHz by a laboratory computer. Analog signals from EOGs and rectified EMGs were sampled after analog-to-digital conversion at a rate of 2 kHz by the computer. Eight consecutive analog values were averaged to obtain a final temporal resolution of 4 msec (0.25 kHz) for data storage. The behavioral relationships of neuronal discharges, digital and analog EMG activity, and EOGs were displayed in each trial on line on the computer video screen in the form of dot displays and analog curves. All data were stored uncondensed on computer disks.

Data analysis

Because of the stereotyped character of phasic responses of DA neurons to external stimuli seen before (Schultz, 1986; Romo and Schultz, 1990; Schultz and Romo, 1990), a standard time window procedure was developed in order to quantify and compare objectively the neuronal responses between different parts of experimentation (Ljungberg et al., 1992). First, onset and offset times of all phasic activations in response to the conditioned stimuli and delivery of liquid reward were determined with a resolution of 4 msec from the first or last of at least three consecutive bins in which activity was above or back to baseline, respectively, as indicated by dot displays, perievent time histograms, and the slopes of cumulative frequency distributions of neuronal impulses. The significance of an increase in activity over baseline was assessed with a specially implemented procedure using the two-tailed Wilcoxon matched-pairs signed-rank test ($p < 0.01$; Schultz, 1986). Depressant responses to stimuli were tested for statistical significance of change in the standard time window, whereas onset and offset times were not measured in view of the low baseline activity of DA neurons.

For subsequent analysis, the standard time window was set to include 80% of onset and offset times of statistically significant increases in activity. Obtained time windows were 88–200 msec after onsets of instruction and trigger lights and 172–256 msec after delivery of liquid reward. Two measures for the responsiveness of neurons were sought. (1) The number of individual neurons showing a significant increase in activity in each time window was obtained with the Wilcoxon procedure. (2) The responsiveness of the whole population of neurons was assessed by measuring the magnitude of change of activity in the time windows against baseline activity for *every* neuron recorded in a particular task situation, independent of a significant response. For both measures, baseline activity was determined during the 500 msec interval preceding presentation of the first stimulus of each trial. All neurons used for determining onset and offset times of significant increases in activity also showed significant activations in the standard time window. Magnitudes determined during the individual durations of response of each *responding* neuron were significantly higher by 20–30% than in the standard time windows for instruction, trigger, and reward used with the same neurons during both learning and established task performance in all three tasks ($p < 0.001$, paired t test).

In addition to the quantitative assessment of responses of individual neurons, the overall responsiveness of the entire population of neurons during particular tasks and learning phases was visually assessed from averages of neuronal activity. A peristimulus time histogram was constructed for every neuron recorded independent of a significant response, and the content of each of its bins was divided by the number of trials to obtain a normalized count. All normalized histograms referenced to the same behavioral event were averaged to obtain the population histogram.

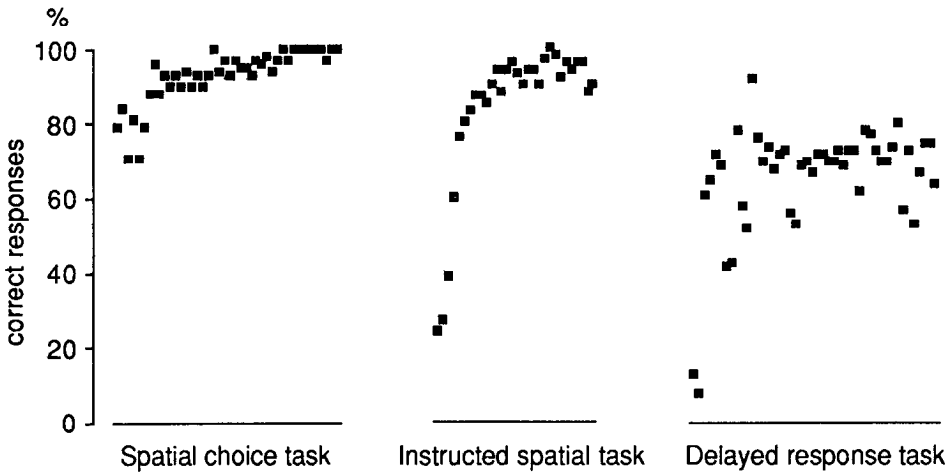

Figure 2. Learning curves for the three tasks in one monkey. Each data point was obtained during the recording of one DA neuron. Tasks were successively employed in the order shown from left to right.

Behavioral performance was assessed during the recording period of every neuron by calculating the median (50th percentile) of reaction time (from trigger light to key release) and movement time (from key release to lever touch) of correct behavioral responses.

Response magnitudes and medians of behavioral parameters were normally distributed (Kolmogorov–Smirnov one-sample test, $p > 0.05$). Parametric statistics were therefore used, which included the means, standard errors of the mean (SEMs), and two-tailed Student's t test for one sample and for paired and unpaired two samples. All timing and magnitude values are given as means ± SEM. Correlations between magnitudes of changes after different stimuli were determined with Spearman's rank correlation coefficient. The χ^2 test was employed for comparing the distributions of fractions of responding neurons among groups A8, A9, and A10 against a hypothetically homogeneous distribution. Neuronal changes obtained from the standard time window method were compared with one-way and two-way ANOVAs using monkeys, phases of experimentation, or midbrain areas as factors. Data from neuronal activity were pooled over the two monkeys when systematic differences were absent.

Histological reconstruction

During the last recording sessions with each animal, small marking lesions were placed by passing negative currents (10–20 μA for 10–20 sec) through the microelectrode immediately after recording from a neuron in the substantia nigra, while larger lesions (20 μA for 20 or 60 sec) were positioned at a few locations above in the same track. This produced distinct patterns of vertically oriented histological marks. Animals were deeply anesthetized with sodium pentobarbital and conventionally perfused with formaldehyde through the heart. Guide cannulas were inserted into the brain at known coordinates of the implant system in order to delineate the general area of recording. The tissue was cut in 50-μm-thick serial coronal sections on a cryotome and stained with cresyl violet. All histological sections were projected on paper, and the outlines of brain structures and the marks from lesions and recent electrode tracks were drawn. Recording positions in tracks marked by electrolytic lesions were reconstructed by using the distances to the lesions according to protocolled micrometer readings. Positions in parallel neighboring tracks were reconstructed at comparable vertical levels. The recorded DA neurons were attributed to groups A8, A9, and A10 according to previous histological descriptions of catecholamine cell groups in the monkey midbrain (Felten and Sladeck, 1983). Thus, group A9 comprised the pars compacta of substantia nigra, whereas group A8 was located dorsolaterally to the substantia nigra in the lateral reticular formation, and group A10 was found dorsomedially adjoining to and incompletely separated from the medial substantia nigra (lateral A10 region of Felten and Sladeck, 1983).

Results

General

Behavior. The gradual learning of each task is illustrated by the learning curves of Figure 2. Errors in the instructed spatial task consisted in precocious release of the resting key before the trigger stimulus, suggesting that animals used the instruction as stimulus for an appropriately delayed movement response. This was probably due to previous overtraining in the reaction time task in which animals moved in response to the first and only stimulus of each trial. In the spatial delayed response task, the interval between instruction and trigger stimuli was prolonged and varied to such an extent that animals only moved in response to the trigger light. Errors in this task mostly consisted in touching the wrong lever.

Performance in the spatial choice task levelled off at almost 100% correct responses, whereas it was successively lower in the two consecutive tasks of higher complexity. Learning of each task was considered to be terminated with a level of performance of 95%, 90%, and 75% correct responses reached in the majority of blocks of trials in spatial choice, instructed spatial, and spatial delayed response tasks, respectively. During established task performance, reaction and movement times in the spatial choice and the instructed spatial tasks were in the same range as in the simple reaction time task employing the same movement (Ljungberg et al., 1992), whereas reaction times were considerably longer in the spatial delayed response task ($p < 0.01$, Fisher test following one-way ANOVA) (Table 1).

Neurons. A total of 239 DA neurons were recorded in group A9 (pars compacta of substantia nigra, $n = 162$), A8 ($n = 38$), and A10 ($n = 39$). Neurons were recorded during learning and established performance of the spatial choice task, followed by recordings during learning and established performance of the instructed spatial task, and subsequently the spatial delayed response task. Histological reconstructions of recording sites revealed unsystematic, statistically insignificant differences in recording areas between tasks, and between learning and established performance of each task (Table 2).

As described before, midbrain DA neurons displayed specific electrophysiological characteristics (Schultz, 1986; Schultz and Romo, 1987). They discharged initially negative or positive impulses with low frequencies (0.5–9 impulses/sec), polyphasic waveforms, and relatively long durations (1.8–5.0 msec). They contrasted with pars reticulata neurons discharging impulses of <1.1 msec duration at rates of 70–90 impulses/sec, a few unknown neurons discharging impulses of <1.0 msec at low rates, and presumptive fibers discharging very short impulses (0.1–0.3 msec).

Table 1. Behavioral performance after established task performance

	Reaction time (msec)	Movement time (msec)	Blocks of trials (*n*)
Spatial choice task			
Monkey A	250 ± 3[1,2]	349 ± 4[1,2]	23
Monkey B	271 ± 3[2]	303 ± 2[2]	32
Instructed spatial task			
Monkey A	224 ± 7[3]	302 ± 5	19
Monkey B	272 ± 7[3]	312 ± 3[3]	16
Spatial delayed response task			
Monkey A	335 ± 3	310 ± 3	31
Monkey B	346 ± 7	277 ± 2	42

Values are given as means ± SEM of performance in individual blocks of trials, each of which contained 40–64 trials. The differences between both monkeys and the three tasks were statistically significant ($p < 0.001$, two-way ANOVA with monkeys and tasks as factors). Separately for each monkey, the following reaction and movement times varied significantly between the three tasks ($p < 0.01$ in Fisher test after one-way ANOVA):

[1], spatial choice versus instructed spatial task;

[2], spatial choice versus spatial delayed response task;

[3], instructed spatial versus spatial delayed response task.

Data from movements to medial and lateral lever were pooled. All measures were obtained in trials in which DA neurons were recorded.

Responses to reward

Of 76 DA neurons recorded during the learning phases of the three tasks, 19 neurons (25%) responded to the delivery of liquid reward. By contrast, after task performance was established only 14 of 163 neurons (9%) were activated by reward (Fig. 3, Table 3). The activity of one neuron was depressed by reward. There were only insignificant differences in reward responses after reaching to the medial versus lateral levers. Of the total of 33 neurons responding to reward, 24 neurons (73%) were also activated by the instruction cue.

The delayed delivery of reward after correct performance showed that reward responses occurred to the delivery of liquid and not to lever touch (Fig. 4, left). The reward response was equally present when reward was delivered simultaneously with correct lever touch. Nine neurons activated by reward in correct trials (235 ± 34%) were also recorded in >10 trials that were

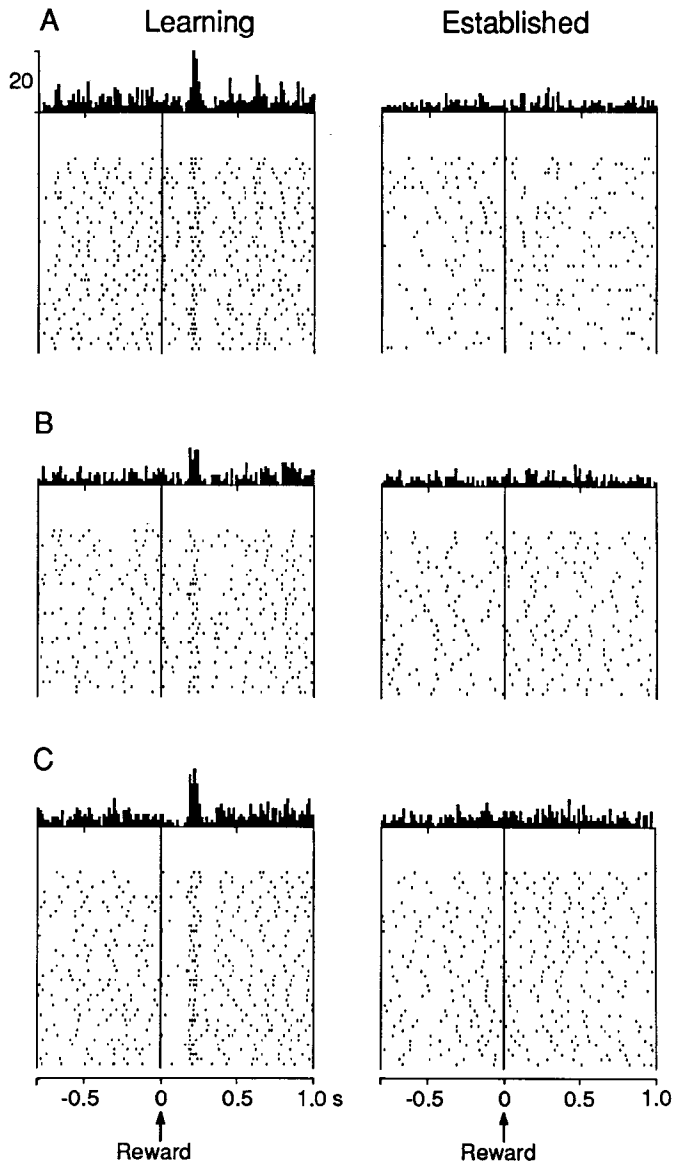

Figure 3. DA neurons respond to reward during learning but not during established task performance. *A*, Spatial choice task. *B*, Instructed spatial task. *C*, Spatial delayed response task. Neuronal activity is aligned on the electronic pulse that drives the solenoid valve delivering the reward liquid. Each panel shows the perievent time histogram and rasters of impulses from one neuron. Distances of *dots* to reward correspond to real-time intervals. Each *line of dots* shows one trial. Trials are pooled over medial and lateral levers that alternated randomly as targets for reaching during the experiment. Neurons shown on the left and right, respectively, belonged to the following groups: *A*, both A9; *B*, A10 and A9; *C*, both A10. Vertical scale is 20 impulses/bin.

Table 2. Regional distribution of neurons recorded in the two monkeys

	Task learning	Established performance
Group		
A8	15 (20%)	23 (14%)
A9	42 (55%)	120 (74%)
A10	19 (25%)	20 (12%)
Midbrain DA zone[a]		
Lateral	6 (8%)	9 (6%)
Intermediate	50 (66%)	125 (76%)
Medial	20 (26%)	29 (18%)
Sum	76 (100%)	163 (100%)

[a] The area of midbrain DA neurons was divided into three equal mediolateral zones.

Table 3. Numbers of neurons responding to reward

	Learning	Established
Spatial choice task	8 of 26 (31%)	2 of 55 (4%)
Instructed spatial task	5 of 22 (23%)	4 of 35 (11%)
Spatial delayed response task	6 of 28 (21%)	8 of 73 (11%)
Sum	19 of 76 (25%)	14 of 163 (9%)

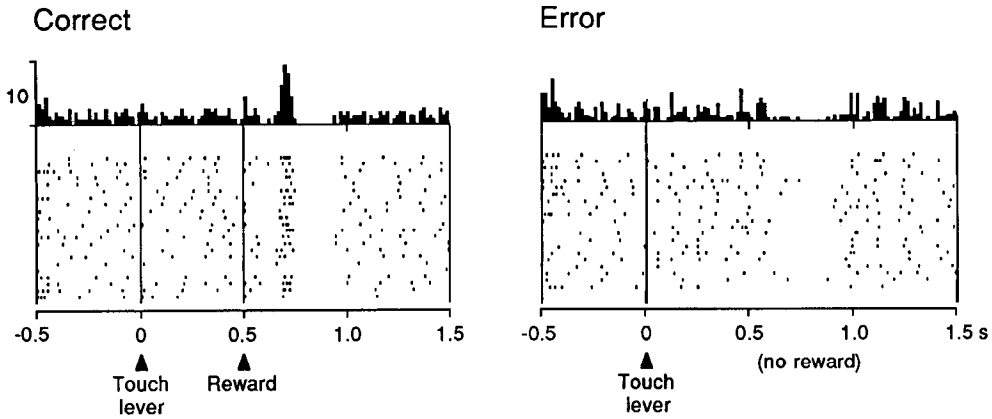

Figure 4. Activating response to reward is replaced by pure depression in erroneous trials at the time of expected reward. *Left*, Reward is delivered 500 msec after correct lever touch. Neuronal activity is aligned on lever touch. *Right*, Both reward delivery and solenoid noise are absent when the wrong lever is touched. Thus, the last stimulus precedes the depression by >0.5 sec. Left and right panels show activity from the same A10 DA neuron during learning of the spatial delayed response task. Vertical scale is 10 impulses/bin.

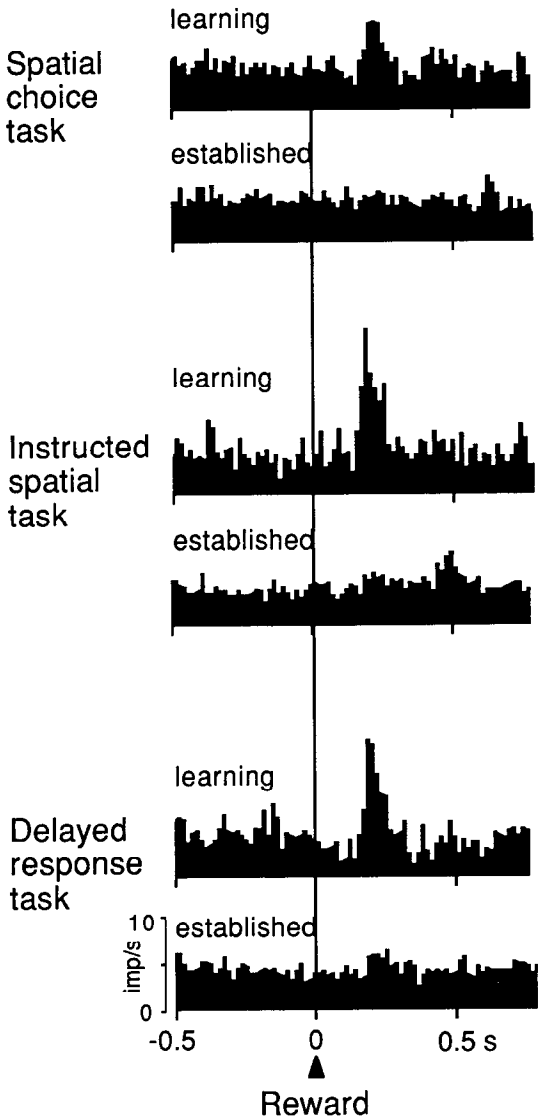

Figure 5. Population responses of DA neurons to reward during learning and established performance of the three tasks. Histograms from each neuron normalized for trial number were added and the resulting sum was divided by the number of neurons. The following data from one monkey were included for spatial choice, instructed spatial, and spatial delayed response tasks, respectively: learning, 853 trials (n = 18 neurons), 264 trials (n = 11), 228 trials (n = 10); established, 1189 trials (n = 23), 803 trials (n = 19), 1198 trials (n = 35). Data were taken from all neurons recorded during each task, were only obtained from correct trials, and were pooled over trials using the medial and lateral levers. Vertical scale denotes impulses/sec.

unrewarded because the incorrect lever was touched. All of them showed depressions of activity at the time at which reward would have been delivered after correct lever touch (mean ± SEM, −59 ± 9%; $p < 0.001$ against 0%, one-sample t test) (Fig. 4, right). Differences between activations in correct and depressions in incorrect trials were significant ($p < 0.001$, paired t test). Thus, the activating reward responses were replaced in error trials by pure depressions at the time of expected reward.

Reward responses in individual neurons showed mean onset latencies of 183 ± 3 msec and lasted for 71 ± 3 msec. There were no significant differences in latency and duration between tasks ($p > 0.01$, one-way ANOVAs). The narrow range and variation of onset latencies and durations suggest a homogeneous temporal response character of DA neurons and allowed us to calculate the average response of all DA neurons studied in each task. This shows that reward responses during but not after learning were sufficiently strong to result in a net response of the whole population (Fig. 5). A similar difference in responsiveness to reward between learning and established performance was found when neuronal activity in the standard time window after reward was compared. Magnitudes of changes in the total neuronal population were significantly higher during learning of all three tasks, as compared to established performance (spatial choice task: 63 ± 14%, n = 26, vs 21 ± 8%, n = 55; instructed spatial task: 106 ± 28%, n = 22, vs 20 ± 7%, n = 35; spatial delayed response task: 60 ± 19%, n = 28, vs 26 ± 9%, n = 73; all $p < 0.001$, t test). Response magnitudes in the time window determined individually for each responding neuron were 242 ± 21% (n = 33). With this 3.5-fold increase, the activity of responding DA neurons increased from about 4.5 impulses/sec baseline to an average of 15 impulses/sec during the response.

Positions of neurons responding to reward in the three tasks are shown in Figure 6. The responsiveness of DA neurons to reward during learning was significantly higher in group A10 than in groups A8 and A9, both in terms of fractions of neurons responding ($p < 0.0001$ in χ^2 test) (Fig. 7) and in magnitudes of changes in the standard time window after reward ($p < 0.01$ in one-way ANOVA). However, the responsiveness during es-

tablished task performance differed insignificantly in both of these parameters between the three groups ($p > 0.1$).

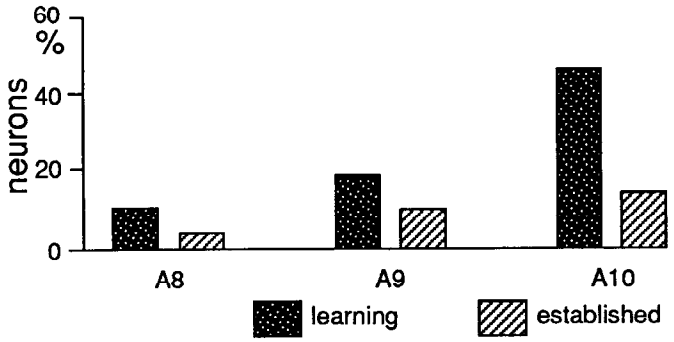
Responses to conditioned stimuli

Established task performance. The responses of DA neurons to instruction and trigger stimuli differed systematically between the three tasks (Fig. 8, Table 4). In the spatial choice task, in which the instruction and the trigger came up simultaneously, activating responses to the combined instruction–trigger stimulus occurred in 26 of 55 DA neurons (47%) (Fig. 8, top). Only two neurons responded with depression of activity.

In the instructed spatial task, in which the trigger stimulus followed the instruction cue with a fixed interval of 1.0 sec, 17 of 35 DA neurons (49%) responded to the instruction cue, whereas only 3 of the 35 neurons (9%) were activated by the trigger stimulus (Fig. 8, middle). Two neurons were depressed by each stimulus. The temporal aspect of the animals' behavior in this task was mainly determined by the instruction cue. This is suggested by the saccadic reaction to the instruction and its absence to the trigger, and by some of the arm movement reaction times that were too short to be related to the trigger stimulus (Fig. 8, middle).

In the spatial delayed response task, the trigger stimulus followed instruction onset with a randomly varying interval of 2.5–3.5 sec, and the instruction cue was only shown for 1 sec. Neuronal responses occurred to both instruction and trigger stimuli and were accompanied by separate ocular reactions to each stimulus (Fig. 8, bottom). Of 73 neurons tested, 28 (38%) showed activating responses to the instruction and 36 (49%) to the trigger, 25 of them being activated by both stimuli. One neuron was depressed by the trigger. The relatedness between instruction and trigger responses is further suggested by the good correlation of magnitudes of changes in the standard time window between instruction and trigger stimuli ($r = 0.8$; $p < 0.01$; Spearman rank correlation test), which contrasts with the weak correlation between the instruction and reward ($r = 0.2$; $p > 0.01$) (Fig. 9).

None of the neurons showed responses that were specifically related to the medial or lateral lever being used (Fig. 10). Magnitudes of responses to the instruction or trigger stimuli in all



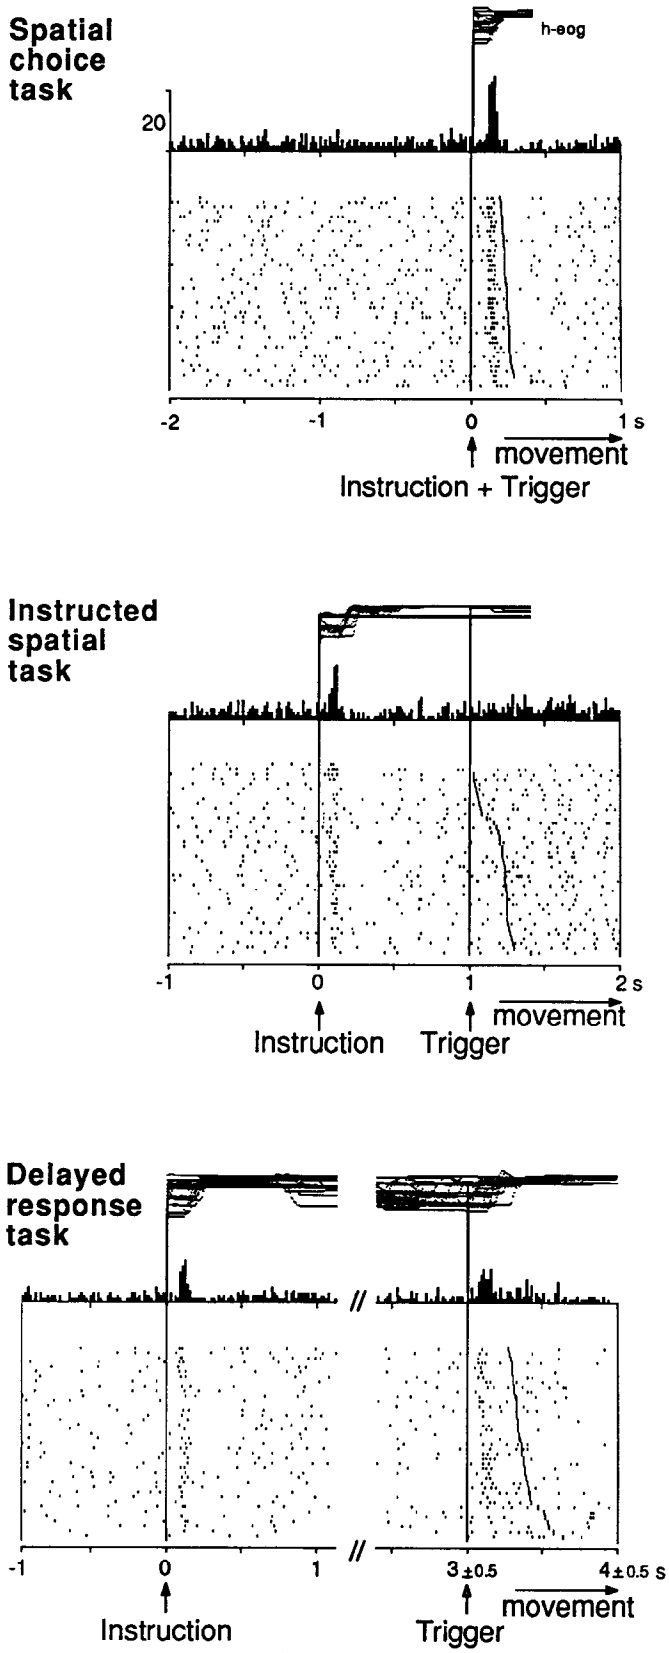


Figure 7. Distribution of DA neurons responding to reward over midbrain cell groups A8–A10 in both monkeys. Neurons from all three tasks are included. *Ordinate* indicates percentage of responding neurons in each cell group. The fraction of neurons responding during learning is significantly higher in group A10, as compared to groups A8 and A9 ($p < 0.0001$, χ^2 test). See Table 2 for numbers of neurons tested.

neurons varied insignificantly in all three tasks between trials using the medial versus the lateral lever.

Responses to instruction and trigger stimuli in the three tasks showed mean onset latencies of 103–112 msec and 101–120 msec, respectively. There were no significant differences between tasks and stimuli ($p > 0.01$, two-way ANOVA), their common mean being 105 ± 2 msec. Durations of instruction responses differed insignificantly between tasks and showed a common mean of 91 ± 3 msec ($p > 0.01$, one-way ANOVA). Durations of trigger responses differed between tasks, being shortest in the instructed spatial task (70 ± 11 msec) and longest in the spatial delayed response task (113 ± 5 msec) ($p < 0.001$, Fisher test after one-way ANOVA). The average response of all neurons recorded in each task illustrates the strong population response to the combined instruction–trigger stimulus during established performance of the spatial choice task, and the slightly weaker responses to individual instruction and trigger stimuli in the two subsequent tasks (Fig. 11). This is also shown by the magnitudes calculated in the standard time window on all neurons recorded. Average magnitudes of changes after the instruction were 126 ± 25%, 75 ± 17%, and 77 ± 12% in the spatial choice, instructed spatial, and spatial delayed response tasks, respectively. Comparable changes after the trigger stimulus were 4 ± 8% and 106 ± 15% in the instructed spatial and spatial delayed response tasks, respectively. Response magnitudes in the time window determined individually for each responding neuron in the three tasks were 277–410% ($n = 71$) and 268–410% ($n = 65$) for instruction and trigger responses, respectively. With this four- to fivefold increase, the activity of responding DA neurons increased from about 4.5 impulses/sec baseline to an average of 17–23 impulses/sec during the response.

Learning. In the spatial choice and instructed spatial tasks, the responsiveness of DA neurons to instruction and trigger stimuli during learning was higher compared to established task

→

Figure 8. Responses of three DA neurons of group A9 to conditioned stimuli during task performance. Superimposed horizontal components of eye movements (*h-eog*) recorded simultaneously with neurons are shown above histograms and rasters of neuronal impulses and illustrate the animal's ocular reaction to stimulus presentation (*up* = eyes to the right). *Small vertical bars* in rasters indicate movement onset (release of resting key). Trials are pooled over medial and lateral levers that alternated randomly as targets for reaching in each block of trials. Trials were ordered off line according to reaction time (from trigger to movement onset). Because of randomly varying intervals between instruction and trigger stimuli (3 ± 0.5 sec), the time base in *C* is split without maintaining the original instruction–trigger interval (rasters separately aligned to instruction and trigger stimuli). Vertical scale is 20 impulses/bin.

Table 4. Numbers of neurons responding to instruction and trigger stimuli

	Learning	Established
Instruction cue		
Spatial choice task	20 of 26 (77%)	26 of 55 (47%)
Instructed spatial task	16 of 22 (73%)	17 of 35 (49%)
Spatial delayed response task	8 of 28 (29%)	28 of 73 (38%)
Sum	44 of 76 (58%)	71 of 163 (44%)
Trigger stimulus		
Spatial choice task	20 of 26 (77%)	26 of 55 (47%)
Instructed spatial task	3 of 22 (14%)	3 of 35 (9%)
Spatial delayed response task	6 of 28 (21%)	36 of 73 (49%)
Sum	29 of 76 (38%)	65 of 163 (40%)

performance, both in terms of fractions of neurons responding and in magnitudes of changes in the standard time windows (Table 4, Fig. 12). In the spatial delayed response task, differences between learning and established performance varied between monkeys, resulting in an overall lower responsiveness during learning.

Recording positions. Positions of neurons recorded from one monkey during the three tasks are shown in Figure 13. During learning of the three tasks, a significantly higher fraction of neurons in group A10 responded to instruction or trigger stimuli, as compared to groups A8 and A9 (both $p < 0.0003$, χ^2 test), although the magnitudes of changes in all neurons tested differed only insignificantly between these three areas ($p > 0.01$, one-way ANOVA) (Fig. 14). Only insignificant regional variations in both the fraction of responding neurons and the magnitudes of changes in all neurons tested were seen during established task performance, for both instruction and trigger stimuli ($p > 0.01$ in both χ^2 and one-way ANOVA tests).

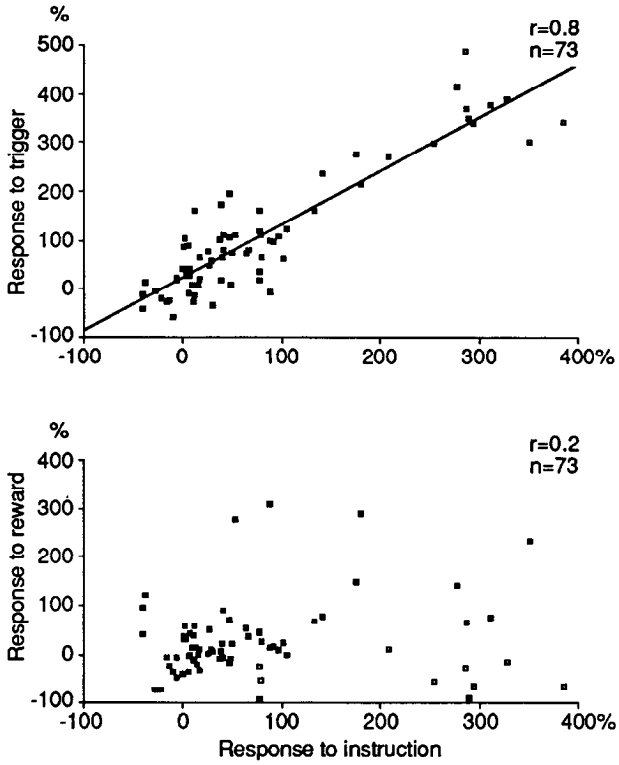

Figure 9. Correlations of magnitudes of neuronal changes between different stimuli. Spearman's rank correlation shows a high coefficient between instruction and trigger stimuli ($r = 0.8$; *top*), but a low coefficient between instruction and reward ($r = 0.2$; *bottom*). Magnitudes of changes in respective standard time windows are shown from all neurons recorded during established task performance in the spatial delayed response task in both monkeys. Mean changes were 77 ± 12%, 106 ± 15%, and 26 ± 9% after instruction, trigger, and reward, respectively.

Discussion

These data show that DA neurons respond to those stimuli that are crucial for learning and performing a behavioral task. In the spatial tasks studied presently, the stimuli effective for activating DA neurons were (1) the delivery of primary reward during learning, which alerts the animal, serves as reinforcer, and indicates correct performance in each task; (2) the instruction cue as first stimulus in each trial, which also provides the necessary spatial information for task performance; (3) the trigger stimulus constituting a conditioned incentive stimulus that predicts reward and elicits an ocular reaction and an arm reaching movement. Most responding neurons were activated by more than one stimulus, indicating that the responses were not selective for the particular behavioral processes associated with the stimuli, such as reinforcement, spatial information, or initiation of movement. Rather, the responses appear to be related to the significance of the stimuli in the particular behavioral situation.

Reward responses during learning

Primary rewards are food objects or fluids that are approached by subjects through innate or instinctive behavior or are learned very early during ontogenesis. Primary rewards may serve to establish and sustain learned behavior, in which case they are called primary reinforcers. A fraction of DA neurons responded to the delivery of primary liquid reward during the learning phase of each of the three successive tasks. The responses were sufficiently frequent and strong to result in a net increase of activity in the whole population of neurons recorded during learning. By contrast, the small fraction of neurons responding to reward during established task performance and their low response magnitude failed to result in such a net population response, suggesting that these responses were little more than random fluctuations in responsiveness among individual neurons. Reward responses during learning occurred more frequently but not exclusively in group A10, suggesting a moderate gradient of responsiveness over groups A8–A10. This might induce a predominant reward-related dopaminergic influence on the postsynaptic structures innervated by A10 neurons, such as the ventral striatum, amygdala, and certain areas of frontal cortex (Szabo, 1980; Porrino and Goldman-Rakic, 1982).

The predominant occurrence of reward responses during the learning phase of each task corresponds to the restriction of similar reward responses to the learning phase of a simple reaction time task (Ljungberg et al., 1992). However, the fraction of responding neurons was only about one-half of that seen during learning of the reaction time task. The present results were obtained in animals trained before in the reaction time task using the same behavioral apparatus (resting key, target lever, mode of reward delivery). It is conceivable that the delivery of reward constitutes a more alerting stimulus for an animal during learning the first task, as compared to learning

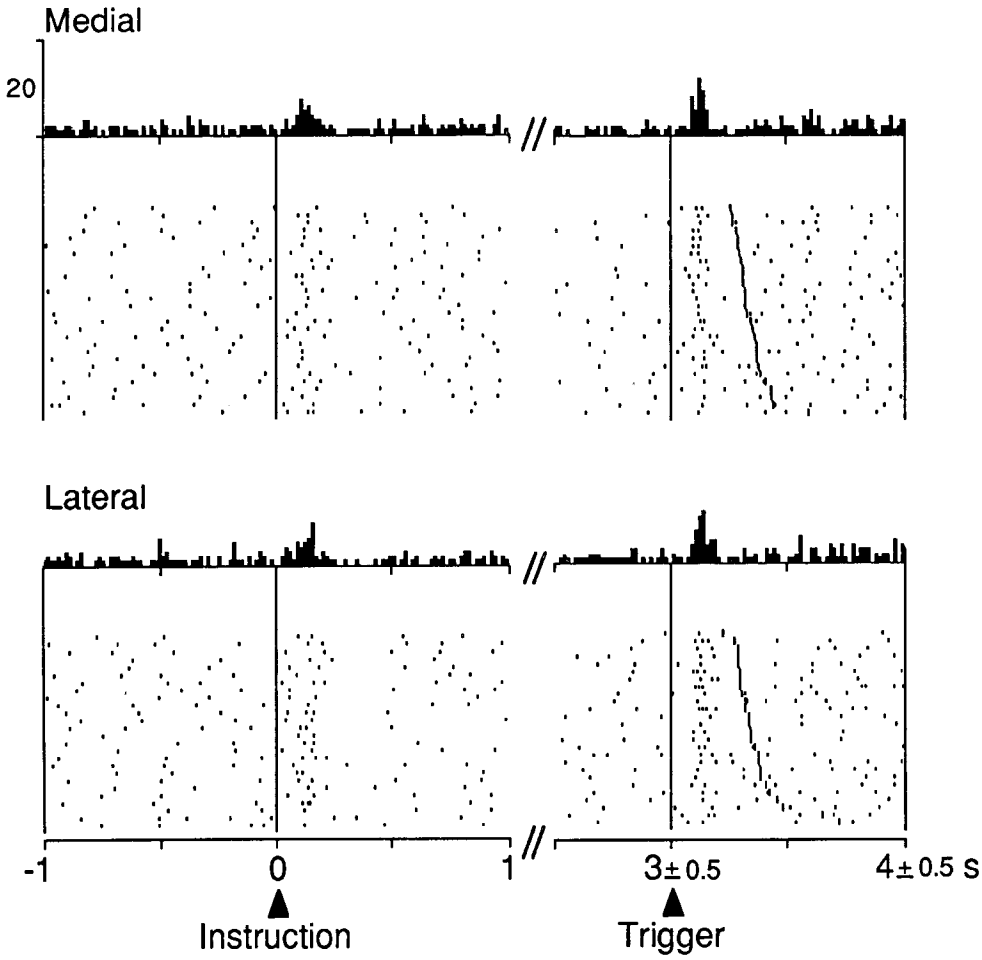

Figure 10. Responses to instruction and trigger stimuli are independent of movement target. Data are from one A9 DA neuron during established performance in the delayed response task. Trials using medial and lateral levers alternated randomly during each block and were separated for analysis and ordered according to reaction time (from trigger to movement onset). *Small vertical lines* in rasters indicate movement onset (release of resting key). Because of randomly varying intervals between instruction and trigger stimuli (3 ± 0.5 sec), the time base is split without maintaining the original instruction–trigger interval. Vertical scale is impulses/bin.

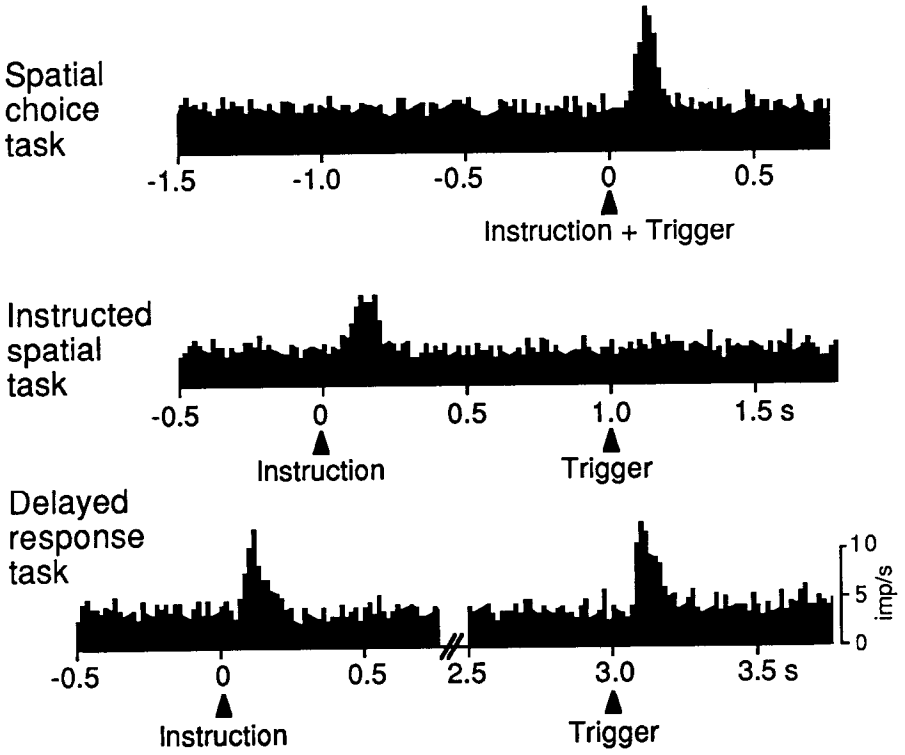

Figure 11. Population responses of DA neurons to instruction and trigger stimuli during established performance of the three tasks. Because of varying intervals, histograms were separately referenced to instruction onset and trigger stimulus for the spatial delayed response task. The following data were included from one monkey for spatial choice, instructed spatial, and spatial delayed response tasks, respectively: 1189 trials ($n = 23$ neurons), 803 trials ($n = 19$), 1198 trials ($n = 35$). Data were taken from all neurons recorded during each task and pooled over correctly performed trials using the medial and lateral levers. Vertical scale is impulses/bin.

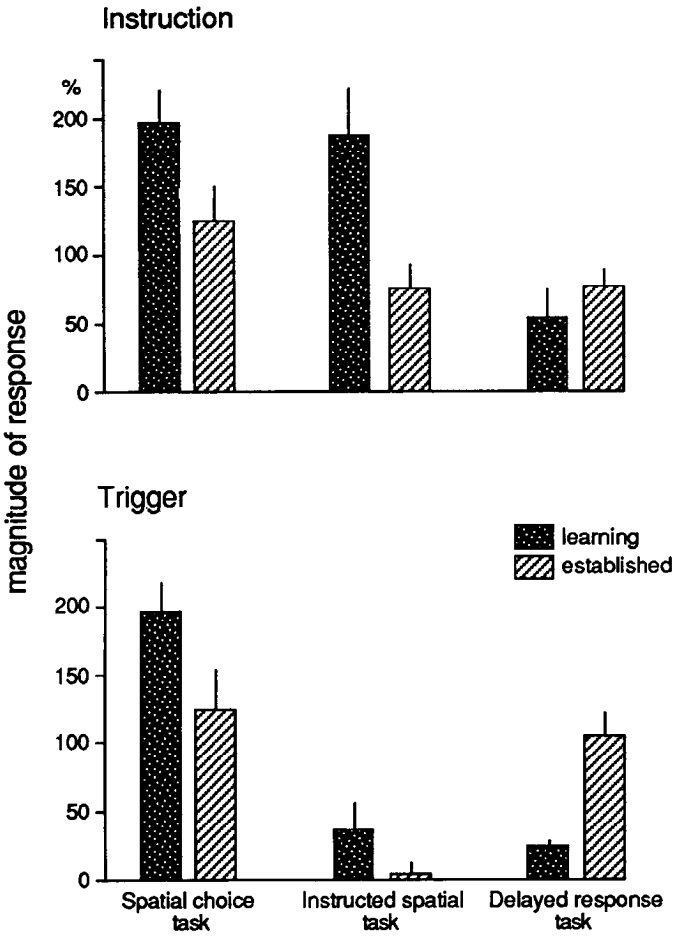

Figure 12. Magnitudes of changes after instruction and trigger stimuli in all neurons tested. The standard time window procedure was employed on all DA neurons tested in both monkeys during learning and established performance of each task, respectively. Differences in magnitudes of changes between learning and established performance were significant for instruction responses in the instructed spatial task ($p < 0.001$, t test), whereas all other comparisons failed to reach this level. See Table 3 for numbers of neurons tested.

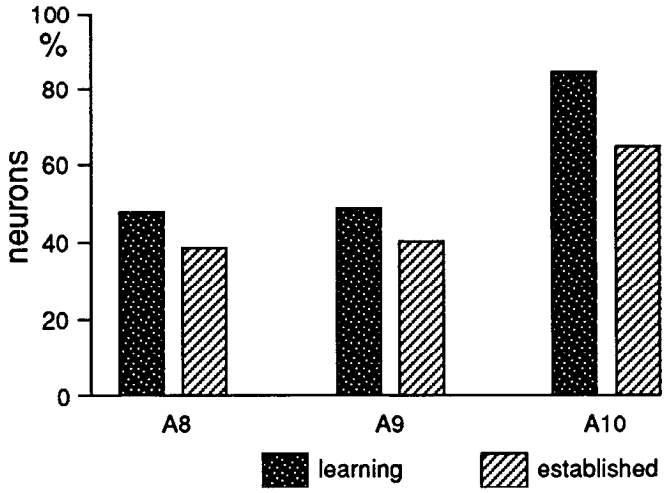

Figure 14. Distribution of DA neurons responding to the instruction cue over midbrain cell groups A8–A10 in both monkeys. Neurons from all three tasks are included. *Ordinate* indicates percentage of responding neurons in each cell group. The fraction of neurons responding during learning is significantly higher in group A10, as compared to groups A8 and A9 ($p < 0.0001$, χ^2 test). See Table 2 for numbers of neurons tested.

the following three tasks in which the arrival of reward and its meaning for task learning are already somewhat familiar.

The fraction of neurons presently responding to reward was also lower than that observed during learning of a delayed alternation task (Ljungberg et al., 1991). This may be due to the double role of reward in that task, serving as both reinforcer and indirect indicator of the next movement target. In agreement with this reasoning, reward responses persisted during established performance of the delayed alternation task, even after overtraining, whereas the present reward responses were largely restricted to the learning phase.

Several arguments suggest that the observed reward responses did not constitute startle responses to stimuli occurring unexpectedly to the animal. Each animal was very familiar with a drop of liquid being delivered at the spout in front of its mouth

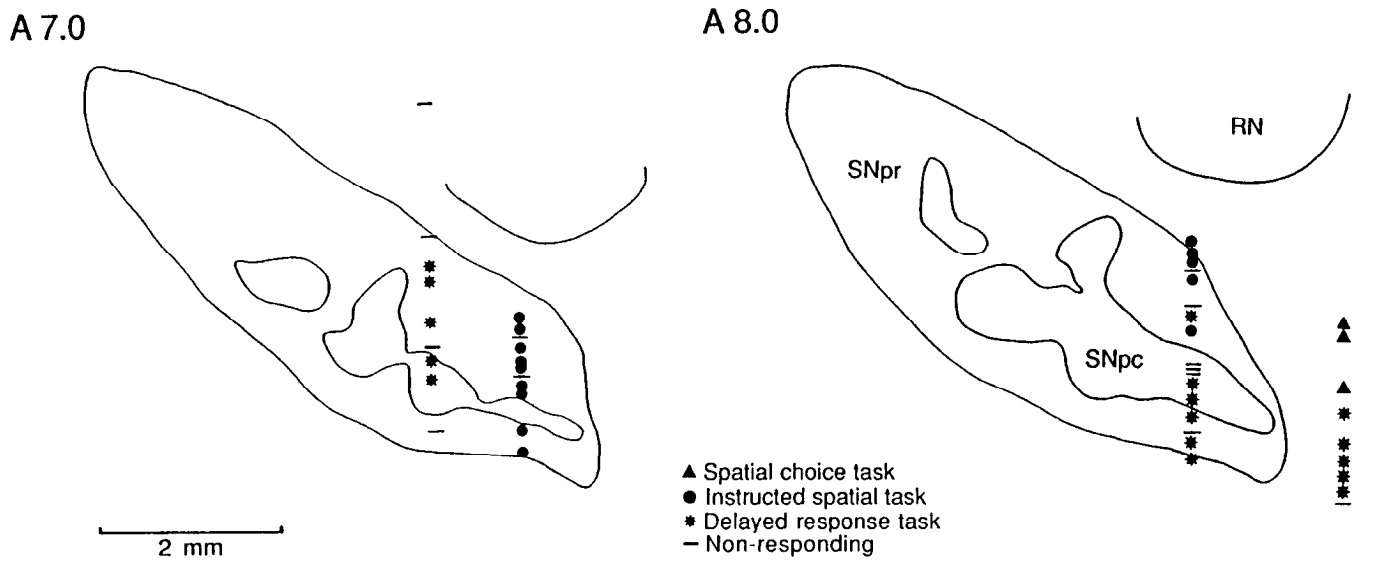

Figure 13. Recording positions of DA neurons with instruction responses during established task performance in one monkey. Positions on two coronal levels are marked separately for each task, whereas nonresponding neurons are commonly labeled by a *dash*. *SNpr* and *SNpc*, pars reticulata and pars compacta of substantia nigra; *RN*, red nucleus.

through its prior learning, performance, and overtraining in the reaction time task with several tens of thousands of trials. Reward responses were largely absent during established task performance and regularly came back with similar frequencies when reward contingencies were changed when advancing from one task to the next one. None of the DA neurons showed response habituation over several tens of consecutive trials, a result that was also seen with all other stimuli effective for activating DA neurons in these tasks. The relation to the delivery of liquid and the lack of relation to stimuli associated with this event are suggested by the effects of closing the liquid tube, as tested in the delayed alternation task (Ljungberg et al., 1991). This manipulation left the noise of the solenoid liquid valve present while blocking liquid flow. DA neurons responding to reward failed to be activated in this situation. A similar specificity for reward was seen before when DA neurons responded to the touch of food reward but failed to be activated by inedible objects (Romo and Schultz, 1990).

An interesting finding was the reproducible depression of activity in error trials occurring in all DA neurons at the precisely the moment when reward would have been delivered in correct trials. The depression did not occur in close temporal relation to a stimulus or a particular behavioral event but appeared as a sharp decrease in activity more than 500 msec after the wrong lever was touched. Reward was normally given at this fixed delay of 500 msec after lever touch throughout the experiment with each animal. It had already been employed for several tens of thousands of trials during learning, established performance, and overtraining of the preceding reaction time task. This suggests that the depression was not a response to the preceding event but reflects a state of expectation of reward at the time of its usual delivery. This would imply that the input to DA neurons had access to centrally stored information concerning the expected time of reward delivery. A similar depression of activity in DA neurons was seen in error trials and in trials with a closed liquid tube during a delayed alternation task (Ljungberg et al., 1991) and when food morsels were replaced by hidden inedible objects (Romo and Schultz, 1990). The visual inspection of rasters and histograms revealed that depressions occurred in many neurons even in the presence of reward responses after correct performance, such that the activating response was added on top of the depressed activity. These depressions were lost together with the activating reward responses after established task performance. This suggests the convergence of two different inputs to DA neurons, one activating input directly driven by the delivery of reward, and one depressant input carrying information about the expected time of arrival of reward but without indicating whether reward was actually delivered.

In conclusion, the restricted occurrence of reward responses during the learning phase and not during established task performance suggests a relationship to the acquisition of new task contingencies. The low responsiveness during established task performance rules out a relationship to general task reinforcement. The fact that many of the same DA neurons also respond to conditioned stimuli important for task performance suggests that reward belongs to a larger class of stimuli effective for activating DA neurons. These stimuli apparently have a particularly alerting and attention-grabbing function for the animal. The particular motivational value of the reception of reward during learning makes this signal a salient stimulus that is very important for the animal when trying to find the new task contingencies. This characteristic appears to determine is capacity to drive DA neurons. Thus, stimuli of prime motivational significance form an important albeit not exclusive class of salient stimuli driving DA neurons. The activity of DA neurons would not selectively transmit information about the reception of primary reward but indicates that a particularly important stimulus occurred in the environment of the subject.

Responses to conditioned stimuli

Whereas reward responses were largely restricted to the learning phase and disappeared with established task performance, responses to the instruction and trigger stimuli occurred throughout both learning and established performance, albeit at varying frequencies. This is probably due to the fact that their behavioral significance was partly known to the animals from the preceding reaction time task. DA neurons failed to respond to known stimuli without any specific meaning for the animal's behavior and only began to respond when the significance of the stimulus became known through learning of the first task (Ljungberg et al., 1992). The change of behavioral significance of familiar conditioned stimuli induced by the modified reward contingencies during the different steps of learning obviously has another impact on DA neurons than the first association of behavioral significance to a familiar but neutral stimulus. The variations of neuronal responsiveness between learning and established performance in each task and between the three tasks should then be related to the changes in behavioral significance of the stimuli during these periods.

Spatial choice task. Animals were familiar with the trigger stimulus from the previous reaction time task (Ljungberg et al., 1992). In the present task, an additional instruction cue was illuminated simultaneously with the trigger stimulus to indicate which of the two levers had to be touched. This visually guided reaching to different targets differed from the single target reaching of the preceding reaction time task and introduced a spatial choice as a first step toward learning the spatial delayed response task. The animal in addition needed to choose between two possible targets in the spatial choice task and thus pay more attention to the conditioned stimuli. Whereas neuronal responses to the trigger stimulus were very low after overtraining of the preceding reaction time task, they reappeared when a spatial choice was required in the present tasks. The increased responsiveness should mainly be due to the increased alerting and attention-grabbing function of the reward-predicting trigger stimulus induced by the changed behavioral situation. We have suggested that responses to triggering stimuli were due to the reward-predicting nature of this conditioned stimulus (Schultz and Romo, 1990; Ljungberg et al., 1992). The present responses to the combined instruction–trigger stimulus are probably not due to the higher sensory impact of two simultaneous visual stimuli, because responses declined again when task performance was established. They should also not be related to the specific spatial information contained in the instruction because they lacked spatial specificity.

Instructed spatial task. As the second step toward learning the spatial delayed response task, the instruction cue indicating the target of reaching was separated by a fixed period of 1 sec from the following trigger stimulus, which determined the moment of reaching. The animal learned to withhold reaching after the instruction cue and wait until the trigger stimulus occurred. This change in the behavioral situation had two effects on DA neurons. Neuronal responsiveness increased again during learn-

ing of this task, and the responses occurred virtually exclusively to the instruction cue and not to the trigger stimulus. Animals reacted with a saccadic eye movement toward the position of the instruction-lever compound and fixated this target until the reaching movement occurred, whereas the trigger stimulus failed to elicit an eye movement. Also, the arm movement began in several trials too soon after the trigger to be elicited by this stimulus. This suggests that the instruction, besides indicating the spatial position, served to trigger a delayed arm movement and that the trigger light had largely lost its unique triggering function and merely served as a temporal reference for the delayed movement. Thus, the neuronal responses to the instruction cue and their absence after the trigger stimulus should be explained by a transfer of the alerting, attention-grabbing, and reward-predicting characteristics from the trigger stimulus to the instruction cue.

Spatial delayed response task. The last step in learning this task involved two modifications. The instruction–trigger interval was randomized and prolonged to 2.5–3.5 sec. A delay was introduced between instruction offset and trigger onset during which task specific information was absent and the animal had to memorize the spatial position of the target lever indicated by the instruction. The response of DA neurons became immediately separated into a response to the instruction and, in the same trial, a response to the trigger stimulus with very similar temporal characteristics. This resulted in a lowering of responsiveness to each stimulus. Responses increased with established task performance, and a slightly higher fraction of neurons responded to the trigger as compared to the instruction cue. The study of eye and arm movements indicated that the two signals had attained different characteristics. The instruction cue was the first stimulus in each trial and also provided important spatial information for correct task performance. It elicited a saccadic eye movement. The trigger stimulus was again a distinctive stimulus that elicited a separate eye movement and the reaching movement toward the target. As principal reward predictor, the trigger stimulus was the main incentive stimulus of the task. However, the instruction cue through its close temporal association with the trigger stimulus and reward may not have been completely devoid of incentive properties.

It is presently unclear whether the stimulus properties of the instruction cue are due to its general role in the delayed response task or are derived from the particular training procedure employed. It also remains to be shown to what extent instruction responses would be reduced with overtraining. In a previous experiment, instruction responses occurred in an asymmetrically reinforced delayed go–no-go task only when the task was occasionally employed, whereas they disappeared with frequent use (Schultz and Romo, 1990). A systematic investigation of responses to instructions in different behavioral contexts would be an interesting way to study the relationship of DA neurons to stimuli not associated with the immediate obtainment of reward.

Role of DA neurons in delay tasks

Previous studies investigating the role of DA in animal cognition found that local DA depletions or local administration of DA receptor antagonists into the prefrontal cortex of monkeys result in impaired performance of spatial delayed response tasks (Brozoski et al., 1979; Sawaguchi and Goldman-Rakic, 1991). During the performance of delayed response tasks similar to the one used presently, prefrontal neurons respond phasically to spatial instruction cues that are being memorized, and to trigger stimuli that induce the recall of stored information and elicit the behavioral response (Fuster, 1973; Kubota et al., 1974; Niki, 1974). Prefrontal neurons also show sustained activity during the instruction–trigger delay, which may reflect processing related to representational task components, such as working memory, expectation of the trigger stimulus, and preparation of the behavioral response. Similar activity is found in striatal neurons during the performance of delay tasks (Alexander, 1987; Schultz and Romo, 1988), including the same spatial delayed response task in the two monkeys used presently (Apicella et al., 1992). DA receptor antagonists reduce and DA itself increases both the phasic responses and the sustained delay activity of prefrontal neurons when applied iontophoretically (Sawaguchi et al., 1990a,b). These combined findings would explain the deficits in delayed response performance after impaired DA transmission and suggest that prefrontal neuronal activity is directly responsible for the performance of delayed response tasks. By contrast, DA neurons failed to show sustained activations during the delay, suggesting that they do not encode the abovementioned representational task components. The phasic responses to instruction and trigger stimuli were not specific for the spatial component of task performance but were apparently related to the salience of these stimuli. Thus, DA neurons appear to enable prefrontal neuronal activity related to representational task components underlying delayed response performance without specifically encoding these components. The mechanisms of this enabling function are presently unknown. It is possible that sustained neuronal activity is facilitated by the action of ionic channels with slow time constants in cortical and striatal neurons (Stafstrom et al., 1982; Calabresi et al., 1987; Kawaguchi et al., 1989; Pennartz et al., 1991) and is built up by cortico–basal ganglia–cortical loops (Romo and Schultz, in press). It would be very interesting to see whether DA may have a specific influence on the time constants of these channels and thus have a regulatory effect on the passage of neuronal activity in these loops.

Behavioral/Systems/Cognitive

Earlier Development of the Accumbens Relative to Orbitofrontal Cortex Might Underlie Risk-Taking Behavior in Adolescents

Adolescence has been characterized by risk-taking behaviors that can lead to fatal outcomes. This study examined the neurobiological development of neural systems implicated in reward-seeking behaviors. Thirty-seven participants (7–29 years of age) were scanned using event-related functional magnetic resonance imaging and a paradigm that parametrically manipulated reward values. The results show exaggerated accumbens activity, relative to prefrontal activity in adolescents, compared with children and adults, which appeared to be driven by different time courses of development for these regions. Accumbens activity in adolescents looked like that of adults in both extent of activity and sensitivity to reward values, although the magnitude of activity was exaggerated. In contrast, the extent of orbital frontal cortex activity in adolescents looked more like that of children than adults, with less focal patterns of activity. These findings suggest that maturing subcortical systems become disproportionately activated relative to later maturing top–down control systems, biasing the adolescent's action toward immediate over long-term gains.

Key words: **accumbens; adolescent; reward; development; orbital frontal cortex; risk-taking**

Introduction

Onset of substance abuse often occurs during the increased risk-taking period of adolescence (Silveri et al., 2004). Little is known to date about neurobiological factors that may predispose adolescents to increased risk-taking behaviors. In adults, mesolimbic regions have been implicated in reward (Knutson et al., 2001; Elliott et al., 2003; McClure et al., 2004), risk-taking (Kuhnen and Knutson, 2005), and addiction (Hyman and Malenka, 2001; Volkow et al., 2004), but less is known about the development of these systems. The purpose of this study was to test the hypothesis that adolescence is a developmental period of increased responsivity to reward relative to childhood and adulthood. Specifically, we examined whether differences in the development of subcortical [e.g., nucleus accumbens (NAcc)] relative to prefrontal [e.g., orbital frontal cortex (OFC)] regions may characterize this period of development to help explain the increase in risk-taking behavior.

Adolescence is characterized by continued structural and functional development of frontostriatal circuitry implicated in behavioral regulation. Periadolescent rats show increases in reward-related dopamine transmission in the striatum (Laviola et al., 1999), and nonhuman primates show increased dopaminergic innervation in the prefrontal cortex (PFC) (Rosenberg and Lewis, 1994, 1995). Human imaging studies show frontostriatal region changes (Giedd et al., 1999; Sowell et al., 1999; Casey et al., 2005) that seem to parallel increased cognitive control (Casey et al., 1997; Rubia et al., 2000; Luna et al., 2001; Luna and Sweeney, 2004; Steinberg, 2004). These changes appear to show activation shifts of prefrontal regions from diffuse to more focal recruitment over time (Casey et al., 1997; Bunge et al., 2002; Moses et al., 2002; Durston et al., 2006). Neuroimaging studies cannot definitively characterize the mechanism of such developmental changes (e.g., synaptic pruning, myelination). However, these volume and structural changes may reflect refinement and fine-tuning of reciprocal projections from these brain regions during maturation. Thus, this interpretation is only speculative.

Recently, neuroimaging studies have begun to examine reward-related processing in adolescents and have shown NAcc activation as shown in adults (Bjork et al., 2004; May et al., 2004; Ernst et al., 2005). However, the results have been mixed as to how adolescents and adults differ in activity. These studies have focused primarily on the region of the accumbens rather than OFC in examining changes. Furthermore, little attention has been given to characterizing NAcc and OFC development from childhood through adulthood. Tracking this development provides additional constraints on whether changes reported in adolescence are specific to this period of development or reflect maturational linear changes.

Here, we used functional magnetic resonance imaging (fMRI) to examine behavioral and neural responses to reward value ma-

nipulations across development. We focused on the NAcc and OFC given previous reports in animal (Hikosaka and Watanabe, 2000; Pecina et al., 2003), imaging (O'Doherty et al., 2001; Zald et al., 2004), and addiction (Hyman and Malenka, 2001) studies implicating them in reward-related learning. Based on rodent models (Laviola et al., 1999; Spear, 2000) and previous imaging work (Ernst et al., 2005), we hypothesized that, relative to children and adults, adolescents would show an exaggerated accumbens response suggestive of refined focal activations within the accumbens during this period, in concert with less mature activations in top–down PFC regions.

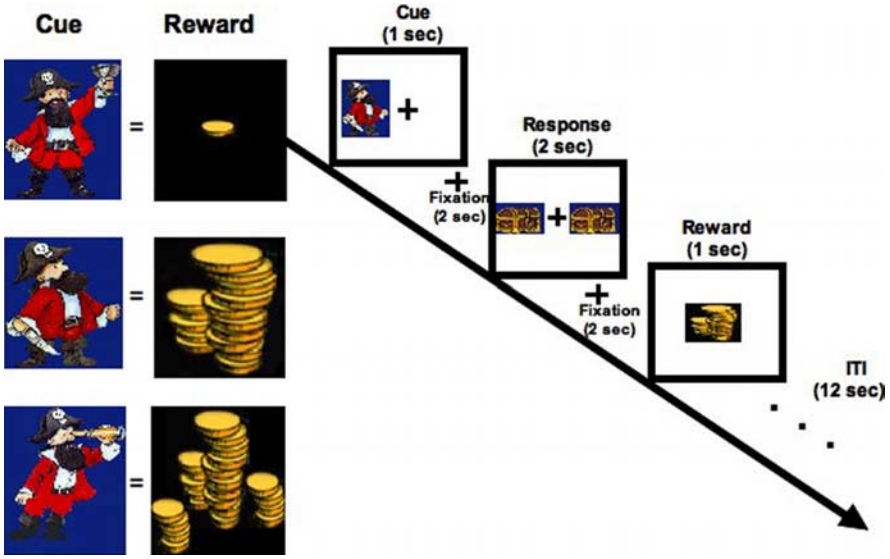

Figure 1. Behavioral paradigm. Left panel, Three cues were each paired with a distinct reward value (counterbalanced across subjects) that remained constant throughout the experiment. Right panel, The paradigm consisted of a cue, response, and reward that were temporally separated in time with 12 s ITI. Total trial length was 20 s.

Materials and Methods

Participants. Sixteen children (seven females; aged 7–11, with mean age of 9.8 years), 13 adolescents (six females; aged 13–17, with mean age of 16 years), and 12 right-handed healthy adults (six females; aged 23–29, with mean age of 25 years) participated in the fMRI experiment. A separate statistical analysis on the adult data was reported previously (Galvan et al., 2005). Three children and one adolescent were excluded from the analysis due to excessive motion (>2 mm). Motion was >0.5 voxels (1.56 mm) in any direction for two subjects (one child and one adult) included in the analysis. Eliminating these subjects from the analysis did not change the results and the different age groups did not differ significantly in in-plane motion (adults: $x = 0.48$, $y = 0.76$, $z = 0.49$; adolescents: $x = 0.26$, $y = 0.58$, $z = 0.45$; children: $x = 0.18$, $y = 0.76$, $z = 0.36$). Subjects had no history of neurological or psychiatric disorder and each gave informed consent (parental consent and child assent for adolescents and children) for a protocol approved by the Institutional Review Board of Weill Cornell Medical College of Cornell University. The experiment on adolescents and children was simulated in a mock scanner before the experiment, in which they were exposed to the sounds they would hear during the actual experiment.

Experimental task. Participants were tested using an adapted version of a delayed response two-choice task previously used in nonhuman primates (Cromwell and Schultz, 2003) and described previously (Galvan et al., 2005) in an event-related fMRI study (Fig. 1). In this task, three cues (counterbalanced) were each associated with a distinct reward value. Subjects were instructed to press either their index or middle finger to indicate the side on which a cue appeared when prompted, and to respond as quickly as possible without making mistakes.

The stimulus parameters were as follows. One of three pirate cartoon images was presented in pseudorandom order on either the left or right side of a centered fixation for 1000 ms (Fig. 1). After a 2000 ms delay, subjects were presented with a response prompt of two treasure chests on both sides of the fixation (2000 ms) and instructed to press a button with their right index finger if the pirate was on the left side of the fixation or their right middle finger if the pirate was on the right side of the fixation. After another 2000 ms delay, reward feedback of either a small, medium, or large amount of coins was presented in the center of the screen (1000 ms). Each pirate was associated with a distinct reward amount. There was a 12 s intertrial interval (ITI) before the start of the next trial. Total trial length was 20 s. Subjects were not rewarded if they failed to make a response or if they made an error; in both cases, they received an error message at the time they would normally receive reward feedback.

Subjects were guaranteed $50 for participation in the study and were told they could earn up to $25 more, depending on performance (as indexed by reaction time and accuracy) on the task. Although the reward amounts were distinctly different from one another, the exact value of each reward was not disclosed to the subject, because during pilot studies, subjects reported counting the money after each trial and we wanted to avoid this possible distraction. Stimuli were presented with the integrated functional imaging system (PST, Pittsburgh, PA) using a liquid crystal display video display in the bore of the magnetic resonance (MR) scanner and a fiber optic response collection device.

The experiment consisted of five runs of 18 trials (six each of small, medium, and large reward trials), which lasted 6 min and 8 s each. Each run had six trials of each reward value presented in random order. At the end of each run, subjects were updated on how much money they had earned during that run. The amount of money earned was consistent across all subjects and all received a continuous schedule of reinforcement (rewarded on 100% of trials). Before beginning the experiment, subjects were shown the actual money they could earn to ensure motivation. They received detailed instructions that included familiarization with the stimuli used. For instance, subjects were shown the three cues and three reward amounts they would be seeing during the experiment. They were not told how the cues related to the rewards. We explicitly emphasized that there were three amounts of reward, one being small, another medium, and another large. These amounts are visually obvious in the experiment because the number of coins in the stimuli increases with increasing reward. Only one subject could articulate the association between specific stimuli and reward amounts, when asked explicitly about this association during debriefing of the subject at the end of the experiment.

Image acquisition. Imaging was performed using a 3T General Electric (Milwaukee, WI) MRI scanner using a quadrature head coil. Functional scans were acquired using a spiral in and out sequence (Glover and Thomason, 2004). The parameters included the following: repetition time (TR), 2000 ms; echo time (TE), 30 ms; 64 × 64 matrix; 29 5 mm coronal slices; 3.125 × 3.125 mm in-plane resolution; flip, 90° for 184 repetitions, including four discarded acquisitions at the beginning of each run. Anatomical T1-weighted in-plane scans were collected (TR, 500; TE, min; 256 × 256; field of view, 200 mm; 5 mm slice thickness) in the same locations as the functional images in addition to a three-dimensional data set of high-resolution spoiled gradient-recalled acquisition in a steady state images (TR, 25; TE, 5; 1.5 mm slice thickness; 124 slices).

Image analysis. The Brainvoyager QX (Brain Innovations, Maastricht, The Netherlands) software package was used to perform a random-effects analysis of the imaging data. Before analysis, the following preprocessing procedures were performed on the raw images: three-dimensional motion correction to detect and correct for small head movements by spatial alignment of all volumes to the first volume by

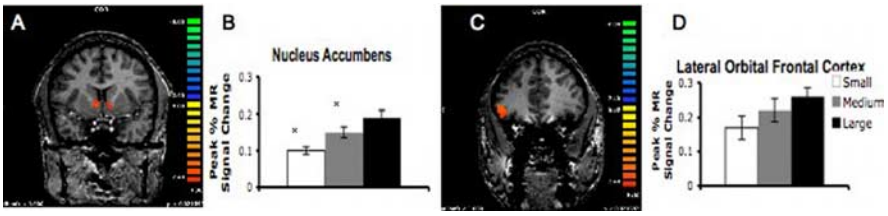

Figure 2. Localization of nucleus accumbens (***A***) and orbital frontal cortex (***C***) activation to reward. There was a main effect of reward value in the nucleus accumbens (***B***) [right ($x = 6, y = 5, z = -2$) and left ($x = -8, y = 6, z = -2$)] but not in the right lateral orbital frontal cortex ($x = 46, y = 31, z = 1$) (***D***). Error bars indicate SEM. Asterisks denote significant differences between small and medium, medium and large, and small and large.

rigid body transformation, slice scan time correction (using sinc interpolation), linear trend removal, high-pass temporal filtering to remove nonlinear drifts of three or fewer cycles per time course, and spatial data smoothing using a Gaussian kernel with a 4 mm full width at half-maximum. Estimated rotation and translation movements never exceeded 2 mm for subjects included in this analysis. Functional data were coregistered to the anatomical volume by alignment of corresponding points and manual adjustments to obtain optimal fit by visual inspection and were then transformed into Talairach space. Functional voxels were interpolated from the acquisition voxel size of 48.83 mm^3 to a resolution of 1 mm^3 during Talairach transformation. The NAcc and OFC were defined by Talairach coordinates in conjunction with reference to the Duvernoy brain atlas (Talairach and Tournoux, 1988; Duvernoy, 1999).

The initial omnibus general linear model (GLM) analysis included all subjects and all runs across the entire trial (relative to pretrial baseline) to determine regions sensitive to reward (NAcc and OFC). To ensure that statistical analyses were performed on the same regions for each age group, separate GLM analyses were performed. Each group showed activation in the NAcc and OFC based on a reward versus baseline contrast. Localization of these regions was further confirmed for each group separately by Talairach coordinates in conjunction with reference to the Duvernoy brain atlas (Talairach and Tournoux, 1988; Duvernoy, 1999) as described above. Previous methodological work has shown that the stereotactic registration and time course of the hemodynamic response across the ages tested in the current study are not dissimilar (Burgund et al., 2002; Kang et al., 2003). Subsequent analysis and *post hoc* contrasts were performed on the regions identified with this initial omnibus GLM for all groups together and then separately for each group. Last, a conjunction analysis was performed that identified the voxels that were commonly activated across all three groups, in the NAcc and OFC (supplemental Fig. 1, available at www.jneurosci.org as supplemental material). The regions of interest identified in the conjunction analysis overlapped with those identified with the initial omnibus GLM, and *post hoc* tests confirmed similar effects as those obtained with the above analyses.

In the whole-group analysis, the omnibus GLM was comprised of all runs across the entire trial (5 runs × 37 subjects = 185 *z*-normalized functional time courses) and was conducted with reward magnitude as the primary predictor. The predictors were obtained by convolution of an ideal boxcar response (assuming a value of 1 for the volume of task presentation and a volume of 0 for the remaining time points) with a linear model of the hemodynamic response (Boynton et al., 1996) and used to build the design matrix of each time course in the experiment. Only correct trials were included and separate predictors were created for error trials. The total number of correct trials for each group was as follows: 1130 for children ($n = 13$), 1061 for adolescents ($n = 12$), and 1067 for adults ($n = 12$). The fewer number of trials for children was corrected by including an additional child subject.

Post hoc contrast analyses were then performed based on *t* tests on the β weights of predictors to identify a region of interest in the NAcc and OFC. Contrasts were conducted with a random-effects analysis. Time series and percent changes in MR signal, across each data point of the entire trial (18 s) relative to 2 s of fixation preceding trial onset (total trial duration was 20 s), were calculated using event-related averaging over significantly active voxels obtained from the contrast analyses. The calculation of number of voxels recruited in each region by age group was based on the GLM analyses conducted on each group described above.

Corrections for multiple comparisons were based on Monte Carlo simulations, which were run using the AlphaSim program within AFNI (Cox, 1996), to determine appropriate contiguity thresholds to achieve a corrected α level of $p < 0.01$ (Forman et al., 1995) based on a search volume of 450 mm^3 for the NAcc. A corrected α level of $p < 0.05$ in the OFC was based on a search volume of ~25,400 mm^3 (Forman et al., 1995). OFC activation did not survive the more stringent threshold of $p < 0.01$ across groups.[a]

Results

Imaging results

The omnibus GLM analysis of the imaging data identified the NAcc [right ($x = 6, y = 5, z = -2$) and left ($x = -8, y = 6, z = -2$)] and right OFC ($x = 46, y = 31, z = 1$) depicted in Figure 2, *A* and *C*, with reward value as the primary predictor, across all subjects and runs of the experiment for the entire trial (18 s), relative to the 2 s intertrial interval preceding the start of the next trial (e.g., reward vs baseline contrast). Within these regions, there was a main effect of reward value ($F_{(2,72)} = 8.424$; $p = 0.001$) (Fig. 2*B*) in the NAcc, but not in the OFC ($F_{(2,72)} = 1.3$; $p = 0.44$) (Fig. 2*D*). *Post hoc t* tests on the main effect of reward for the NAcc confirmed significant differences between the large and small ($t_{(36)} = 4.35$; $p < 0.001$), large and medium ($t_{(36)} = 2.01$; $p < 0.05$), and medium and small ($t_{(36)} = 2.09$; $p < 0.04$) rewards, with greater activation for greater rewards.

Developmental differences in magnitude and extent of activity to reward

Because the focus of this study was on how reward influences neural recruitment across development, we examined developmental differences in the magnitude and extent of accumbens and OFC activity for trials to the largest reward. The magnitude of activity was calculated as a percent change in MR signal averaged across the first 18 s of the trial relative to the intertrial interval of fixation immediately preceding the trial (2 s), which was averaged across the entire experiment (90 trials = 900 scans). This calculation was performed for each group. The extent of activity was calculated as the volume of activity (number of voxels) across runs, by group, using the same contrast.

Magnitude of activity. In the accumbens and OFC, there were significant developmental differences in percent change in MR signal ($F_{(2,22)} = 6.47$, $p < 0.01$; $F_{(2,22)} = 5.02$, $p = 0.01$, respectively) (Fig. 3*A*,*B*). In the accumbens, adolescents showed the greatest signal change. *Post hoc* tests confirmed significant differences between adolescents and children ($t_{(11)} = 4.2$; $p = 0.03$) and between adolescents and adults ($t_{(11)} = 5.5$; $p = 0.01$) in magnitude of accumbens activity. In the OFC, *post hoc* tests confirmed significant differences between children and adolescents ($t_{(11)} = 4.9$; $p = 0.01$) and children and adults ($t_{(11)} = 3.99$; $p = 0.01$). Thus, adolescents showed enhanced activity in the accumbens and this pattern differed from that in the OFC and from children and adults.

Extent of activity. There were significant developmental differ-

[a]Cluster sizes of 6 and 10 for the accumbens and OFC, respectively, were determined by these simulations. Cluster sizes of 8 and 10 in the adolescent and child data, respectively, survived more stringent thresholds ($p < 0.002$ and $p < 0.001$, respectively). In the OFC, cluster sizes of 14 and 18 in adolescents and children, respectively, survived more stringent thresholds ($p < 0.004$ and $p < 0.001$, respectively).

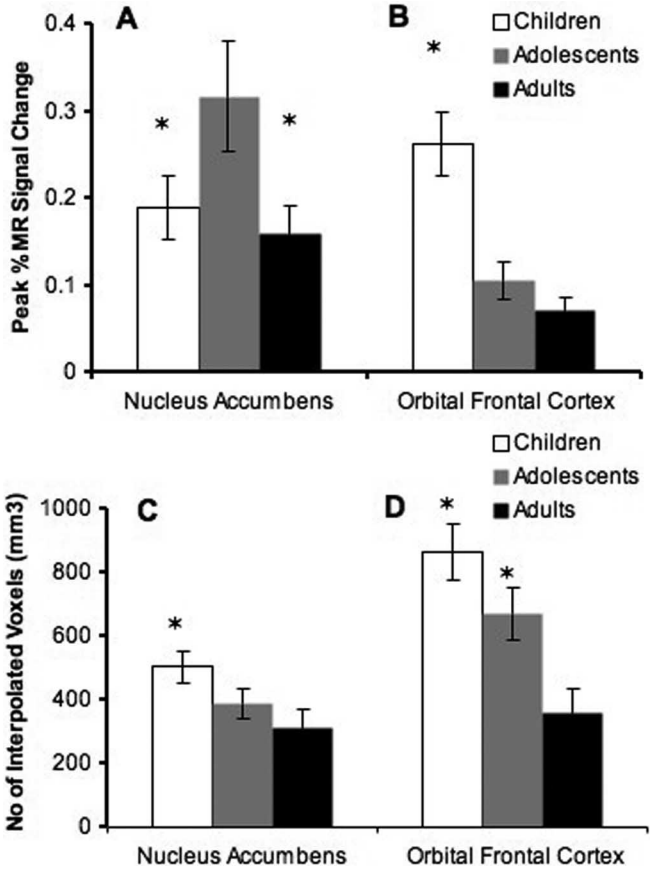

Figure 3. Magnitude and extent of accumbens and OFC activity to reward. ***A***, Adolescents showed exaggerated percent change in MR signal to large reward relative to children and adults in the accumbens. ***B***, In the OFC, children had the greatest percent change in MR signal relative to adolescents and adults. ***C***, Children showed the largest volume of activity in the accumbens relative to adolescents and adults. ***D***, Children and adolescents showed greater volume of activity in the OFC relative to adults. Error bars indicate SEM. Asterisks denote significant activation differences between children and adolescents and adolescents and adults in ***A***; greater activation in children relative to adolescents and adults in ***B***; greater volume of activity in children relative to adolescents and adults in ***C***; and greater volume of activity in children relative to adolescents and adolescents relative to adults in ***D***.

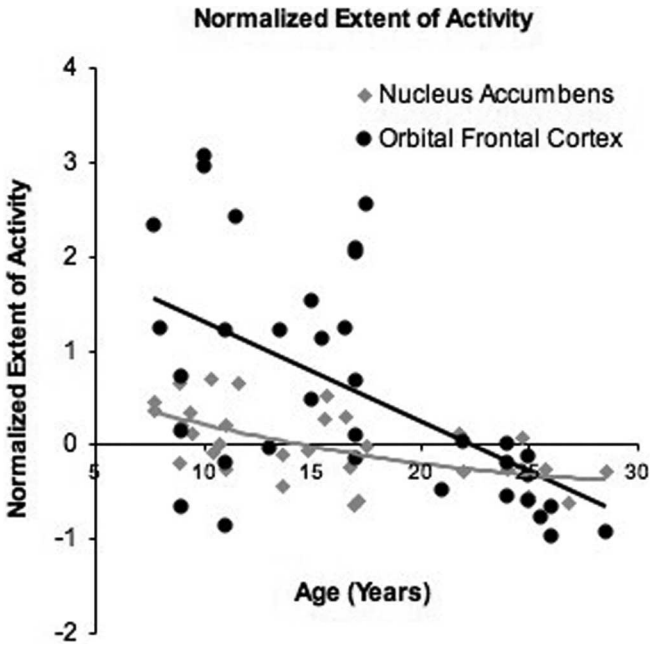

Figure 4. Normalized extent of activity measure for the nucleus accumbens and OFC for all subjects, adjusted for the average extent of activity (x − mean/mean) for each region.

ences in the extent of activity in the accumbens ($F_{(2,22)} = 4.7$; $p < 0.02$) and OFC ($F_{(2,22)} = 5.01$; $p = 0.01$). *Post hoc* tests confirmed the largest volume of activity in the accumbens for children (503 ± 43 interpolated voxels) relative to adolescents (389 ± 71 interpolated voxels) ($t_{(22)} = 4.2$; $p < 0.05$) and adults (311 ± 84 interpolated voxels) ($t_{(22)} = 3.4$; $p < 0.05$) (Fig. 3*C*). Adolescents and adults did not differ ($t_{(22)} = 0.87$; $p = 0.31$). For the OFC, children (864 ± 165 interpolated voxels) ($t_{(22)} = 7.1$; $p = 0.01$) and adolescents (671 ± 54) ($t_{(22)} = 5.8$; $p = 0.01$) showed the largest extent of activity relative to adults (361 ± 45 voxels) (Fig. 3*D*), but there were no significant differences between children and adolescents ($t_{(22)} = 1.8$; $p = 0.07$). This pattern of activity reflects protracted development of OFC relative to the NAcc (Fig. 4, graph).

Developmental differences in temporal processing of reward value

To examine differential changes in neural recruitment throughout the experiment, we examined the main effect of, and interactions with, time (early, middle, and late trials) on MR signal change in the NAcc or OFC. The effect of time was observed only in the interaction of time by group by reward in the accumbens ($F_{(8,136)} = 3.08$; $p = 0.003$) and less robustly in the OFC ($F_{(8,136)} = 2.71$; $p = 0.02$). This interaction was driven primarily by changes occurring during the late trials of the experiment (for changes as a function of early, middle, and late trials, see supplemental Fig. 2, available at www.jneurosci.org as supplemental material). Figures 5 and 6 depict the temporal course of change in MR signal as a function of small, medium, and large reward values for late trials by group for each region. These time series show an exaggerated change in accumbens activity in adolescents relative to children or adults for the small and large reward trials that occurs ~5–6 s after the response and the point in which all three age groups show a change in MR signal. This pattern is illustrated graphically in Figure 7 for clarity (for change in OFC activity at this time point for all three age groups, see supplemental Fig. 3, available at www.jneurosci.org as supplemental material).

Behavioral results

The effects of time on task and reward value were tested with a 5 (runs) × 3 (small, medium and large reward) × 3 (group) ANOVA for the dependent variables of mean reaction time for correct trials and mean accuracy. There were main effects of reward value ($F_{(2,72)} = 9.51$; $p = 0.001$) and group ($F_{(2,220)} = 4.37$; $p = 0.02$) and significant interactions of reward by time ($F_{(8,288)} = 4.176$; $p < 0.001$) and group by reward by time ($F_{(16,272)} = 3.01$; $p = 0.01$) for mean reaction time. The main effect of reward showed that, across all subjects, mean reaction times were faster to the largest reward (mean, 515.47; SD, 178.75; $t_{(36)} = 3.8$; $p < 0.001$) relative to medium (mean, 556.89; SD, 180.53) or small reward (mean, 552.39; SD, 180.35). The significant interaction of reward by time was driven primarily by the three-way interaction of group by reward by time. Adults differed in mean reaction time to all three reward values by the end of the experiment (Fig. 8). Adolescents were significantly faster to the large relative to the medium and small rewards with no difference between the medium and small rewards. The children showed no significant differences in mean reaction time to the small, medium, or large rewards. There were no significant correlations

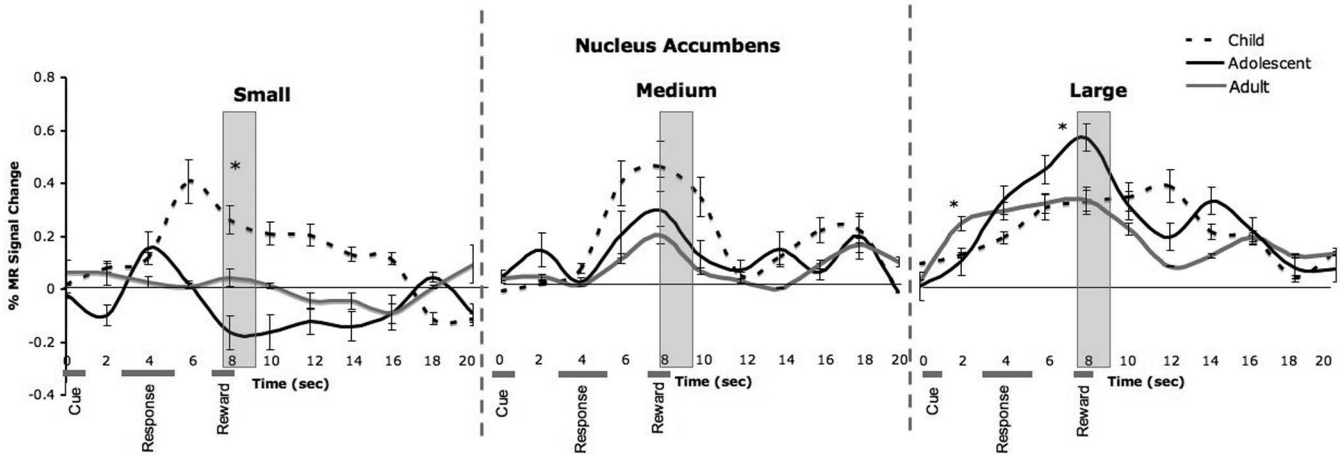

Figure 5. Temporal changes in the nucleus accumbens as a function of small, medium, and large reward values for late trials of the experiment for each age group. The gray bars correspond to the point(s) ~5–6 s after the response. Error bars indicate SEM. Asterisks denote activation differences between groups.

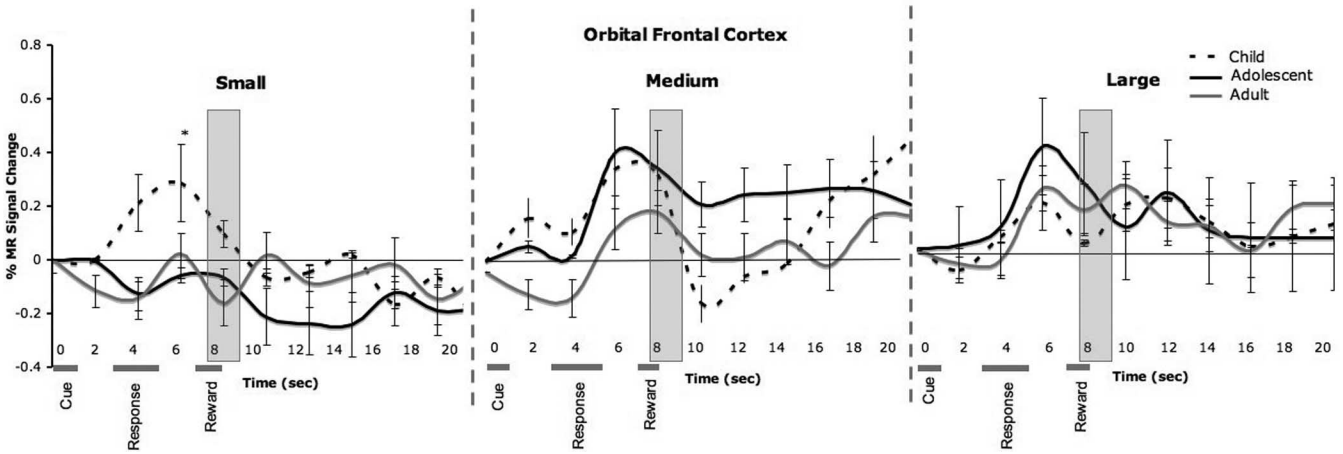

Figure 6. Temporal changes in the orbitofrontal cortex as a function of small, medium and large reward values for late trials of the experiment for each age group. The gray bars correspond to the point(s) ~5–6 s after the response. Error bars indicate SEM. Asterisks denote activation differences between groups.

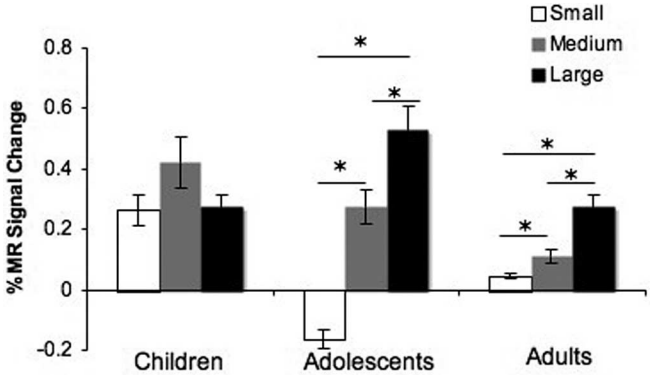

Figure 7. Percent change in MR signal ~5–6 s after the response relative to pretrial baseline for each age group, showing an exaggerated change in accumbens activity in adolescents relative to children or adults for the small and large reward trials. Error bars indicate SEM. Asterisks denote activation differences between groups.

between mean reaction time or accuracy and accumbens or orbitofrontal activity.

There were no significant effects of reward ($F_{(2,72)} = 0.26$; $p = 0.40$), group ($F_{(2,220)} = 0.73$; $p = 0.80$), or time ($F_{(4,476)} = 0.57$; $p = 0.44$) or interactions for mean accuracy. All subjects had high accuracy across reward values (children: small, 96%; medium, 98%; large 96%; adolescents: small, 98%; medium, 99%; large, 99%; and adults: small, 98%; medium, 99%; large, 99%).

Discussion

This study examined behavioral and neural responses to reward value manipulations across development. Our findings support our hypothesis that adolescents differ from children and adults in NAcc and OFC recruitment, regions previously implicated in reward processing (Knutson et al., 2001) and addiction (Volkow et al., 2004). Our results are consistent with rodent (Laviola et al., 2003) and previous developmental imaging (Ernst et al., 2005) studies of enhanced accumbens activity during adolescence. These findings suggest that different developmental trajectories for these regions may relate to the increased impulsive and risky behaviors observed during this period of development.

Developmental changes in structure and function

Enhanced accumbens activity was paralleled by a refined pattern of activity for adolescents relative to children, but similar to adults. In contrast, adolescents showed more diffuse OFC recruitment more similar to children than adults. We interpret these data to suggest that the NAcc development may precede that of the OFC during adolescence. Protracted development of

prefrontal regions, with a transition from diffuse to focal recruitment is consistent with MRI-based neuroanatomical (Sowell et al., 1999; 2003; Gogtay et al., 2004) and fMRI studies (Casey et al., 1997, 2002; Brown et al., 2005, Durston et al., 2006) of prefrontal development (Casey et al., 2005).

Developmental changes in volume of activity within frontostriatal regions (Sowell et al., 1999) are interesting in light of known developmental processes (e.g., dendritic arborization, synaptic pruning, myelination) occurring during this period. However, neither fMRI nor MRI provide a level of analysis with which to definitively characterize the mechanism of such changes. The volume measures were used in part to constrain the interpretation of magnitude differences, but we can only speculate that our changes in volume and magnitude of activity of the NAcc and OFC reflect a fine-tuning of this circuitry with experience and development.

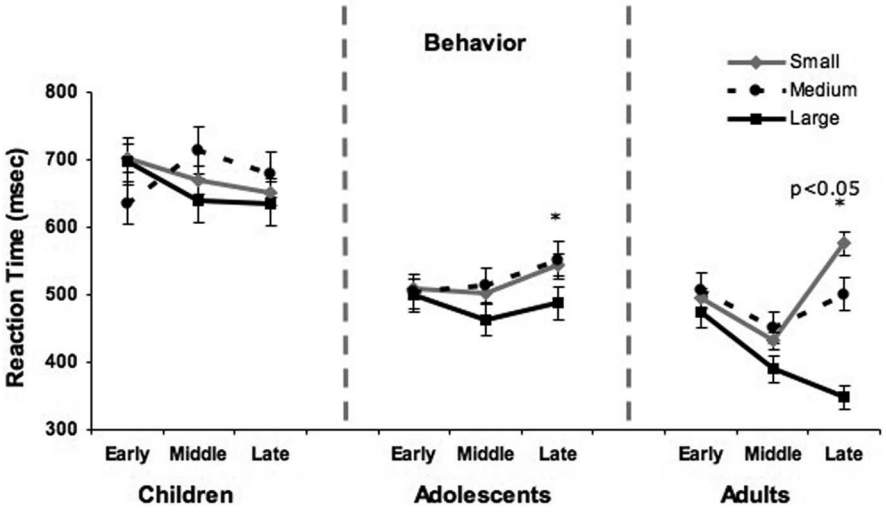

Figure 8. Behavioral results. Mean reaction time as a function of small, medium, and large reward values are shown for early, middle, and late trials of the experiment for each age group. Error bars indicate SEM. Asterisks denote slower reaction time to small and medium rewards relative to small in adolescents and slower reaction time to small relative to medium and medium relative to large in adults.

Differential recruitment of frontostriatal regions has been reported across several developmental fMRI studies (Casey et al., 2002; Monk et al., 2003; Thomas et al., 2004). Typically, these findings have been interpreted in terms of immature prefrontal regions rather than an imbalance between prefrontal and subcortical regions. Given evidence of prefrontal regions in guiding appropriate actions in different contexts (Miller and Cohen, 2001) immature prefrontal activity might hinder appropriate estimation of future outcomes and appraisal of risky choices, and might thus be less influential on reward valuation than the accumbens. This pattern is consistent with previous research showing elevated subcortical, relative to cortical activity when decisions are biased by immediate over long-term gains (McClure et al., 2004). Furthermore, accumbens activity has been shown to positively correlate with subsequent risk-taking behaviors (Kuhnen and Knutson, 2005).

Reward-related learning across development

One goal of this study was to characterize reward learning across development. Adults showed behavioral distinction to the three cues, with fastest responses to the large reward cue. Adolescents showed less discrete responses and children show little to no learning. Slower learning across development parallels the imaging results of protracted OFC development that may hinder associative learning between predictive events and reward outcomes. This interpretation is supported by animal (Hikosaka and Watanabe, 2000; Chudasama and Robbins, 2003; Cetin et al., 2004; Hosokawa et al., 2005) and human imaging (Elliott et al., 2000; O'Doherty et al., 2003; McClure et al., 2004; Cox et al., 2005; Galvan et al., 2005) studies showing the role of the OFC in learning and representing links between predictive events (stimuli and responses) and reward outcomes in optimizing choice behavior.

Few imaging studies of reward to date have been able to show differences in behavior as a function of reward outcome (Haruno et al., 2004; Delgado et al., 2005; Galvan et al., 2005). Here, our data suggest that reward-related neural responses influence behavioral output. Minimal behavioral variability might have precluded previous authors from determining whether different reward conditions bias behavioral output. One reason we were able to tease apart behavioral differences might be because our paradigm was designed to maximize behavioral responses and learning by using a continuous reinforcement schedule (Dickinson and Mackintosh, 1978; Gottlieb, 2004, 2005). Animal studies show faster learning with continuous relative to intermittent reinforcement schedules (Gottlieb, 2004) that may have explained the faster responses to large reward trials across subjects and the distinct pattern of behavior for each reward value in the adults by late trials.

Rewards are relative for different contexts and ages

Reward preference varies based on the reward context (Tversky and Kahneman, 1981; Tremblay and Schultz, 1999). Evidence from our study supports the notion that relative reward preference is exaggerated during adolescence: adolescents showed an enhanced accumbens response to the large reward and a decrease in activity to the small reward relative to other rewards and to other ages. Adolescents report greater intensity of positive feelings and more positive BOLD signal intensity than adults during a win condition (Ernst et al., 2005). The adolescents may have viewed the small reward as an omission of reward, similar to lack of an expected event at a given time, previously shown to decrease striatal activity (Davidson et al., 2004). This finding corresponded to a slowing of reaction time from early to late trials for the smaller rewards, providing additional evidence that this condition may have been perceived as more negative for adolescents. Together, these findings imply that reward perception might be influenced by changes in neural systems during adolescence (Irwin, 1993).

Developmental changes may parallel changes with learning

Recently, Pasupathy and Miller (2005) showed that, in monkeys, striatal areas detected reward contingencies first, which then seemed to bias prefrontal regions into taking action. Other work has shown that the OFC seems to be implicated in linking responses with outcomes (Elliott et al., 2000; Galvan et al., 2005). However, this effect may be dependent on maturity of prefrontal systems and reciprocal connections between frontostriatal re-

gions (Haber, 2003) that associate actions with outcome, because children and adolescents did not show learning, as indexed by mean reaction time, to the extent that adults did. It remains an open question whether the children could not learn to discriminate between the different reward values or whether they were just as happy with a small reward as a large reward.

The findings of less sensitivity in the behavioral response than in the neural response in the younger subjects may be consistent with previous learning studies showing that neural changes precede behavioral changes (Tremblay et al., 1998). The adolescents were significantly faster to larger reward trials by the end of the experiment relative to the other reward values, but the accumbens showed distinct patterns of activity to each reward value similar to adults. If this explanation were true, we might expect with additional training that the adolescents' behavioral performance would ultimately parallel the accumbens activity. Likewise, one would expect similar patterns to emerge in children, but with more extensive training.

Contrasts between current and previous findings

Although the exaggerated accumbens response in adolescents replicates those of May et al. (2004) and Ernst et al. (2005), Bjork et al. (2004) found decreased accumbens activity relative to adults during a gain versus no gain contrast. Whereas Bjork et al. (2004) reported MR signal change over the entire experiment, we examined MR changes across the entire experiment and also during early and late trials, with the later trials showing greater activation in adolescents relative to adults.

A second difference in the current study, relative to the existing literature (O'Doherty et al., 2001, Elliott et al., 2003, Galvan et al., 2005), was the lack of a main effect of reward value in the OFC across subjects. In examining this main effect, we collapsed OFC activity across age groups and across the experiment. Other reward studies of the OFC have not included developmental populations, who have diffuse and more variable patterns of activity in this region (Casey et al., 1997). Inclusion of developmental populations thus increased the variability in recruitment of this region, with less consistent patterns of OFC activity. Furthermore, our data showed that, for later trials of the experiment, OFC activity differed for larger relative to smaller rewards, but showed a less precise mapping to reward value relative to the NAcc, which showed discrete patterns of activity to each reward value across age groups, consistent with our previous work (Galvan et al., 2005) and that of others (Elliott et al., 2003).

Implications

Our results suggest that there are protracted maturational changes in top–down control systems relative to subcortical regions implicated in appetitive behaviors. These different developmental trajectories may contribute to suboptimal choices in adolescents being driven more by appetitive systems than control systems (Spear, 2000). Understanding the development of structural and functional connectivity of reward-related mesolimbic circuitry may further inform the field on the neurobiological basis of increased reward-seeking and adolescent-onset addiction.

A neural framework similar to the one we propose here has been suggested to explain addiction. Accordingly, the PFC is "hijacked" by an impulsive subcortical system, which might render it unable to appropriately modulate decisions in the context of future consequences (Bechara, 2005). Our findings are consistent with this speculation but occur during typical development. Thus, disproportionate contributions of subcortical systems relative to prefrontal regulatory systems may underlie poor decision-making that predisposes adolescents to drug use and, ultimately, addiction.

Shadows Cast by Retinal Blood Vessels Mapped in Primary Visual Cortex

Daniel L. Adams* and Jonathan C. Horton

The mammalian eye is a remarkable optical device, but its design is not perfect. The blood vessels that supply the inner retina are located in front of the photoreceptor layer, blocking access to light. Their shadows create a pattern of blindness in the field of vision that corresponds precisely to the location of the largest vessels in the eye. We show here that in squirrel monkeys, focal deprivation by blood vessels leads to rewiring of the eye's geniculocortical projections, imprinting an image of the retinal vascular tree onto the primary visual cortex. This process illustrates vividly that local imbalances in neuronal activity can influence column formation during normal development.

In many higher species, the geniculate afferents serving right and left eyes are segregated in the brain in layer 4 of primary (striate, V1) visual cortex into a mosaic of interdigitated inputs called ocular dominance columns (*1*). The formation of these columns has been scrutinized in the hope of elucidating the processes that guide the development of the cerebral cortex (*2*). Some experiments show an essential role for neuronal activity, because infusion of tetrodotoxin into both eyes seems to prevent the emergence of ocular dominance columns (*3*). According to this idea, the correlated discharge of neighboring ganglion cells, perhaps generated by spontaneous waves of retinal activity (*4*, *5*), induces local cortical imbalances in the density of geniculate afferents driven by each eye. These small imbalances may be amplified by competitive synaptic interactions between geniculocortical afferents to generate a mature system of ocular dominance columns (*6*–*9*).

Doubt has been cast on this explanation for column development by recent experiments showing that ocular dominance columns appear in ferrets despite early bilateral enucleation (*10*). This finding suggests that column formation is ordained by intrinsic molecular cues, and not by patterns of neuronal activity. Although neuronal activity has a disputed role in column induction, it certainly can influence column morphology at a later stage in development. Raising a newborn animal with monocular eyelid suture, to mimic congenital cataract, causes shrinkage of the deprived eye's columns and expansion of the normal eye's columns (*11*–*14*). Here, an imbalance in neuronal activity has a profound influence on the shape and size of the ocular dominance columns. The relevance of these experiments, however, can be questioned on the grounds that suture of the eyelids is an artificial manipulation, creating an extreme imbalance in the stimulation of each retina. It has not been shown that under natural circumstances, competition between the two eyes has an important influence on the appearance of the ocular dominance columns.

Cortical representation of retinal vessels. We now show that visual deprivation occurs routinely in normal primates, affecting ocular dominance patterns. Helmholtz discovered while plotting his blind spot that he could discern the proximal stumps of large blood vessels emerging from the optic disc (*15*). With refinement of perimetric techniques, subsequent investigators have plotted these so-called angioscotomas over wide portions of the visual field (*16*, *17*). The hemoglobin in red blood cells absorbs light, casting a shadow from blood vessels in the inner retina onto photoreceptors located underneath. We have found a representation of angioscotomas in striate cortex of the squirrel monkey (*Saimiri sciureus*).

The squirrel monkey was reported originally to lack ocular dominance columns (*18*, *19*). They are present, in fact, but often appear poorly developed and irregular (*20*). To examine their pattern more closely, we enucleated one eye and stained striate cortex for the mitochondrial enzyme cytochrome oxidase (CO) (*21*–*23*). The ocular dominance columns are revealed by this approach because metabolic activity is reduced in the missing eye's columns. After perfusion, striate cortex was stripped from the white matter, flattened in a single piece, and sectioned tangentially to the surface. Flatmount preparations enhance the likelihood of detecting subtle metabolic patterns, such as the optic disc representation, which lies buried in the calcarine sulcus (*24*).

Ocular dominance is expressed most strongly in layer 4C of striate cortex. CO montage of this layer revealed a fuzzy pattern of fine ocular dominance columns (Fig. 1). The left eye's optic disc representation appeared as a large, homogeneous zone of CO activity in the right cortex. It stained darkly, because the left eye was enucleated in this animal. In the periphery, a large pale zone corresponded to the representation of the far nasal retina of the left eye (monocular crescent).

Radiating from the optic disc representation were more than a dozen, thin, dark profiles. They represented the blood vessels emanating from the optic disc of the left eye. This was confirmed by matching each element in the cortical pattern to its corresponding retinal blood vessel (Fig. 1, C and D).

How do angioscotoma representations form? Angioscotoma representations cannot form before birth, because the uterine environment is dark. We propose that after birth (Fig. 2A), the right cortex, for instance, receives binocular input organized into nascent columns, except at the representation of the left optic disc, where input comes exclusively from the right eye. Once the baby monkey opens its eyes (Fig. 2B), light enters through the pupil and shadows are cast by retinal blood vessels. Ganglion cells in the left eye that receive input from photoreceptors beneath blood vessels are not driven effectively by visual stimulation. In turn, these ganglion cells fail to activate lateral geniculate neurons. Consequently, the axon terminals of these geniculate fibers retract in striate cortex, and the territory they relinquish is taken over by afferents serving the right eye. After the critical period, geniculocortical afferents become frozen in place. When one eye is enucleated (Fig. 2C), CO reveals the ocular dominance columns, which have been rearranged to correspond to the cortical representation of retinal blood vessels.

To confirm this hypothesis, we double-labeled the ocular dominance columns in this animal (and two others) by injecting an anatomical tracer, [^{3}H]proline, into the remaining right eye (*25*, *26*). The proline and CO patterns were identical (compare Figs. 1A and 3). As expected, the angioscotoma representations in striate cortex were solidly labeled, as intensely as the blind spot representation (Fig. 2C). This experiment proved that cortical angioscotoma representations are generated by anatomical rearrangement of geniculocortical inputs. It should be emphasized that in three control animals, with intact vision in both eyes, no CO pattern was visible in layer 4C. Removal of one eye is required to reveal the cortical angioscotoma representations with CO.

Angioscotomas were represented in striate cortex of 9 of 12 squirrel monkeys. Shadows generated in the contralateral eye

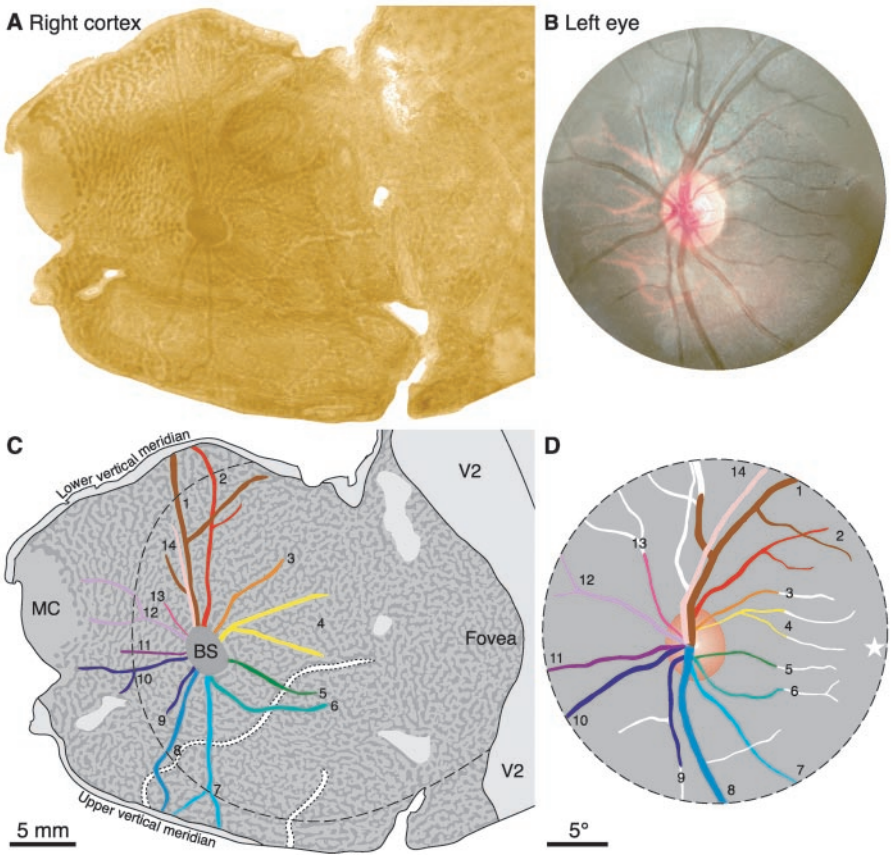

Fig. 1. Representation of angioscotomas in striate cortex. (**A**) Flatmount montage stained for CO after removal of the left eye to reveal the ocular dominance columns. The dark lines emerging from the central dark oval correspond to the blood vessels of the left eye. (**B**) Fundus photograph showing optic disc and retinal blood vessels. (**C**) Drawing of vessel representations, color-coded to match the retinal drawing. Dashed line denotes circumference of retinal photograph in (B), projected onto the cortex. MC, monocular crescent; BS, blind spot. (**D**) Drawing of retina, with represented portions of vessels coded by color. Star denotes the fovea.

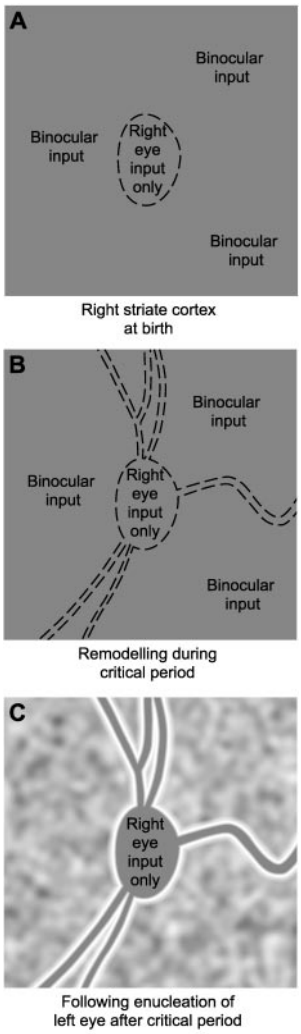

Fig. 2. CO staining of angioscotoma representations. (**A**) At birth, CO staining is uniform. Angioscotomas are absent, but the right eye already monopolizes the left eye's blind spot representation. (**B**) After light exposure, vessels begin to cast shadows, generating angioscotoma representations. Their pattern becomes immutable at the end of the critical period. (**C**) Removal of one eye induces an undulating pattern of CO activity, corresponding to the ocular dominance columns. The angioscotomas appear silhouetted against this textured background, because they stain solidly. Note the tendency for the other eye to "frost" the vessel and blind spot representations.

predominated, because blood vessels are generally larger in nasal retina, especially near the optic disc. A few vessel representations, however, could be traced across the vertical meridian (V1/V2 border) and into the opposite cortex (Figs. 3 and 4). Their contrast was reversed, compared with other angioscotomas in the same cortex, because they originated from the temporal retina of the ipsilateral eye.

Each angioscotoma representation was fringed by cortex that exhibited opposite CO contrast (Fig. 5). This "frosting" enhanced the visibility of the angioscotoma pattern by highlighting each vessel representation. Apparently, when retraction of geniculate afferents occurs during the critical period, the displaced afferents form a solid phalanx along the edges of the representation of each angioscotoma. The displaced afferents dominate in these flanking zones, expelling those from the other eye. This is noteworthy, because neither eye enjoys any obvious competitive advantage in visual stimulation right next to an angioscotoma.

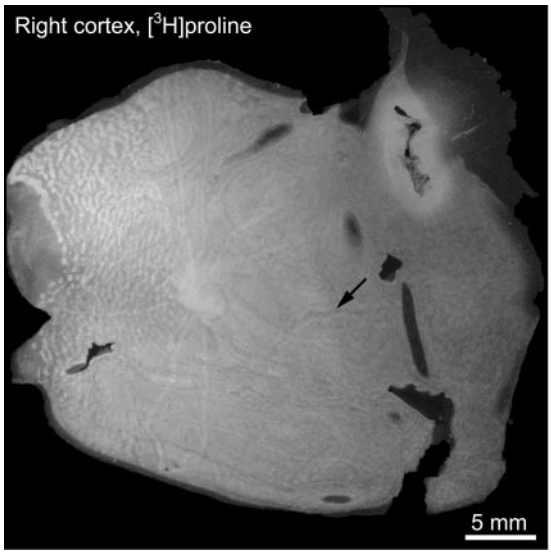

Fig. 3. Autoradiograph prepared after tracer injection into the remaining right eye, showing label (bright regions) distributed in a pattern identical to that in Fig. 1A. The congruence of the patterns confirms that CO staining after monocular enucleation precisely reflects the distribution of geniculocortical inputs. The angioscotomas and the blind spot are solidly labeled, as predicted in Fig. 2C. Arrow denotes an unlabeled angioscotoma, arising from a temporal vessel in the right eye.

Precision of the visual field representation. The biggest vessels represented in the cortex were retinal veins near the optic disc. They attained a diameter of nearly 100 μm (0.62°). The smallest were vessels approaching the fovea, less than 30 μm wide (0.17°). To calculate shadow widths, we measured exit pupil diameter, distance from exit pupil to retinal vessel, retinal vessel diameter, and distance from retinal vessel to photoreceptors (*27*, *28*). Many smaller vessels failed to eclipse the pupil completely and therefore produced no umbra. For example, a 28-μm-diameter vessel 7.5° from the fovea cast only penumbra, measuring 83 μm in width (Fig. 6). From an expression for cortical magnification factor along an isoeccentricity ring

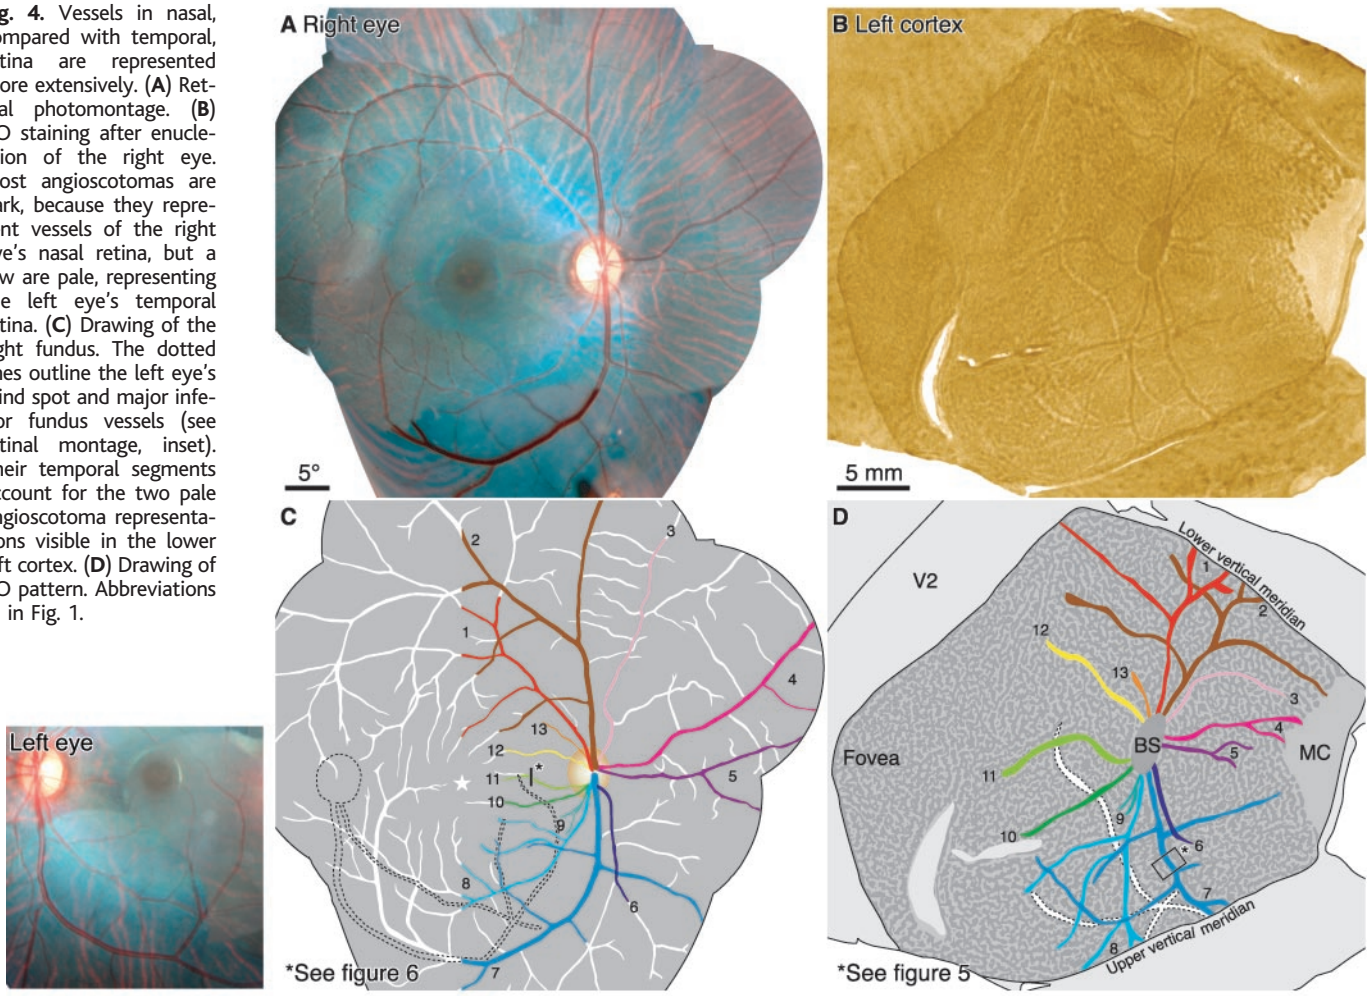

Fig. 4. Vessels in nasal, compared with temporal, retina are represented more extensively. (**A**) Retinal photomontage. (**B**) CO staining after enucleation of the right eye. Most angioscotomas are dark, because they represent vessels of the right eye's nasal retina, but a few are pale, representing the left eye's temporal retina. (**C**) Drawing of the right fundus. The dotted lines outline the left eye's blind spot and major inferior fundus vessels (see retinal montage, inset). Their temporal segments account for the two pale angioscotoma representations visible in the lower left cortex. (**D**) Drawing of CO pattern. Abbreviations as in Fig. 1.

(derived below), we calculated that an 83-μm shadow should produce a cortical representation 737 μm wide. In fact, the vessel's cortical profile measured only 350 μm (see vessel 11, Fig. 4D), indicating that just the central ~50% of the shadow was sufficiently dense to induce remodeling of geniculocortical afferents. This portion of the shadow was only three to four cones wide.

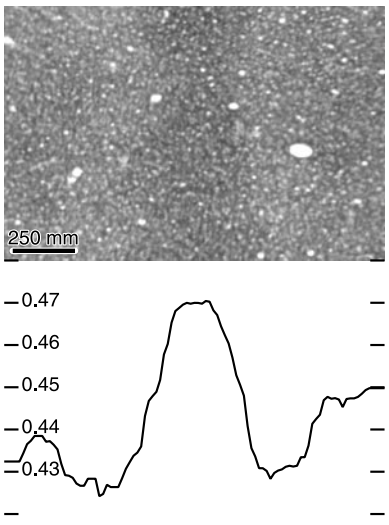

Fig. 5. Vessel representations are flanked by CO activity of opposite contrast. A vertically oriented dark angioscotoma representation (Fig. 4D) is surrounded by pale staining. Mean optical density of each column of pixels is plotted below.

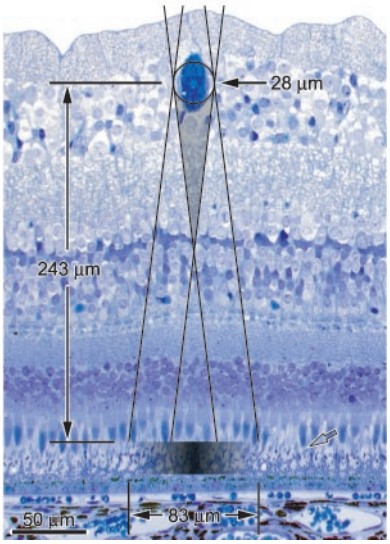

Fig. 6. Optics of shadow formation. Toluidine blue–stained retinal cross section (Fig. 4C), showing the shadow cast by a blood vessel in the ganglion cell layer with a 28-μm lumen diameter, when fully inflated. Pairs of lines, projected from opposite margins of a 1.9-mm pupil located 8.4 mm in front of the retina, show the boundaries of the shadow obscuring photoreceptors. The umbra (gray triangle) does not reach the photoreceptor layer in this example, because the vessel is too small. Gradient indicates penumbra, which reached a maximum optical density of 0.45. Open arrow shows the light-recipient boundary between cone inner and outer segments.

Generation of a retinotopic map. The angioscotoma representations provided a simple means for construction of a visual field map in striate cortex (Fig. 7). First, dozens of prominent landmarks, such as vessel crossings or bifurcations, were identified in the retina and projected onto a tangent screen to determine their eccentricity. These data were used to calibrate a system of rings and rays, which was superimposed on an image of the nasal retina. This image was transformed by computer to match retinal features precisely to their cortical representation (*29*), thereby generating a retinotopic map. This map is truly retinotopic, as opposed to visuotopic, and therefore immune to errors introduced by eye movements or inaccurate plotting of receptive fields (*30*).

Areal cortical magnification factor, M_a, was derived by measuring the area (mm^2) of each compartment in the map and dividing by the area (degrees squared) of its corresponding visual field zone. The data were plotted as a function of eccentricity (Fig. 7D) for four hemispheres from two monkeys. Cortical magnification factor in the squirrel monkey was similar to the value reported in the macaque (*31*), showing that these evolutionarily divergent primate species emphasize macular vision to the same extent.

Discussion. Retinal blood vessels give rise to angioscotomas in the visual field, just as the optic disc creates a blind spot. However, the mechanism is quite different. The

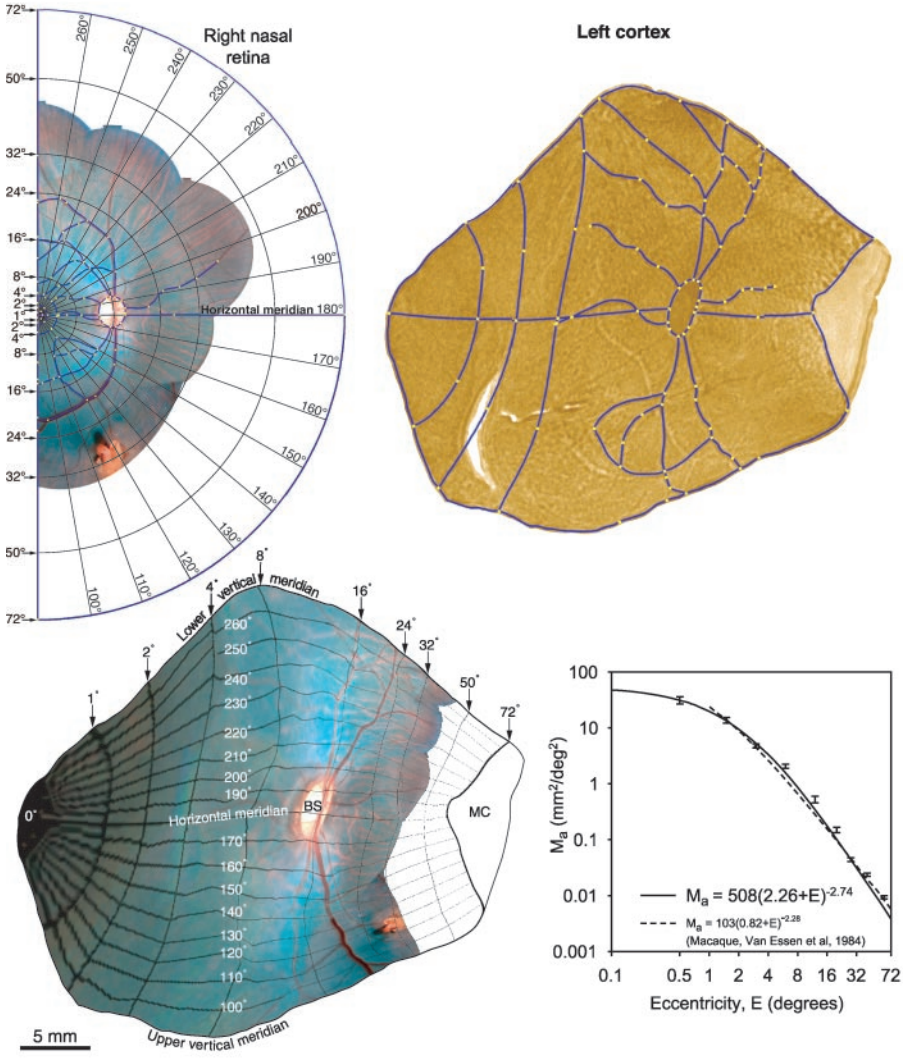

Fig. 7. Generation of a retinotopic map. Ring and ray pattern is superimposed on the right retina, using landmarks plotted in vivo. Correspondence points (yellow squares) are placed on matching features of the retina and cortex. Blue lines are placed on segments between correspondence points. They include blood vessels, vertical meridian (V1/V2) border, horizontal meridian, and the boundary between binocular and monocular cortex (measured in vivo at 72°). Warping of the retina onto the cortex produces a retinotopic map. Areal cortical magnification factor (mean ± SEM) for four cortices is graphed versus eccentricity.

optic disc produces a hole, devoid of ganglion cells, in the fabric of the retina. The other eye fills in the cortical gap, visible as a solid oval amid a sea of ocular dominance columns. This occurs in utero, before visual experience has any influence (*32*).

Angioscotomas, on the other hand, arise because a few photoreceptors are condemned to a life of idleness owing to their location beneath blood vessels. The retina is otherwise normal. Deprivation by vascular shadows induces local remodeling of geniculate afferents, in a cortical distribution that corresponds to the trajectory of blood vessels within the retina. The process is analogous to amblyopia induced by a congenital cataract. A lens opacity, however, provokes global shrinkage of geniculate afferents in the cortex (*33*). Our results show that amblyopia can be exquisitely focal within an eye. It probably occurs underneath retinal blood vessels in primates other than squirrel monkeys, including humans.

Angioscotoma representations in the cortex provide a natural example of how visual activity can influence the pattern formed by ocular dominance columns. They are essentially nothing more than long, threadlike ocular dominance columns, generated because deprivation in one eye tips the local competition for cortical territory in favor of the other eye. The deprived eye is compensated by preferential assignment of the closest adjacent territory—as reflected by the "frosting" lining the angioscotoma representations (Fig. 5). This phenomenon presumably reflects an innate tendency to allot cortical territory in a reciprocal manner (*6*–*8*, *34*, *35*). The global periodicity of the columns resulting from this process is probably under genetic control (*36*). However, our data show that local imbalances in neuronal activity can determine the precise layout of the columns in any given region of cortex.

We have searched in vain for angioscotoma representations in striate cortex of the macaque and human. In general, these species have larger ocular dominance columns than squirrel monkeys. In the macaque, we have projected the retinal vasculature onto striate cortex, to compare the predicted size of individual vessel representations with the width of ocular dominance columns. The ocular dominance columns are much larger. We speculate that because the columns are larger, their pattern is resistant to the influence of angioscotomas during development. In the macaque, the amount of cortex deprived by angioscotomas is simply too small to compel the rearrangement of ocular dominance columns. Nonetheless, shouldn't an angioscotoma carve a narrow swath through any column, no matter how big? Apparently, this is prevented by the higher degree of segregation of geniculocortical afferents in macaques, compared with squirrel monkeys. In squirrel monkeys, the fine grain and weak segregation of the ocular dominance columns create perfect conditions for the formation of angioscotoma representations.

Amblyogenic shadows just a few cones wide were represented in the cortex, reflecting the remarkable precision of the visual field map in layer 4C (*37*). In other layers, angioscotomas were not visible, because of the coarser resolution of the visual field map and the intermingling of ocular channels. The representation of angioscotomas was most extensive at eccentricities from 4° to 30°. Within this range, an ideal balance exists between cortical magnification factor and blood vessel size. Beyond 30°, vessel size and magnification factor both decrease, so most angioscotoma representations disappear. Toward the fovea, blood vessels rapidly taper. Their reduction is offset by a steep rise in cortical magnification factor, but nevertheless, angioscotoma representations abruptly peter out at 3° to 4°. This occurs because vessels near the fovea contain too little blood to cast a sufficiently dense shadow.

Angioscotomas are rarely noticed in our vision because they are filled in perceptually, just like the blind spot. Remarkably, angioscotomas amount collectively to a greater portion of the visual field than the blind spot. Nature has struck a compromise in the design of the eye, by allowing blood vessels to obscure some photoreceptors. At least the largest vessels in the retina are prohibited from approaching the fovea, so that we are scarcely aware of their presence.

21. Experiments were performed on 12 adult squirrel monkeys from the California Regional Primate Center, Davis, CA. All procedures were approved by the University of California, San Francisco, Committee on Animal Research. Each animal was anesthetized with 2% isoflurane and paralyzed with succinylcholine (45 mg/kg, intravenously). The animal was placed in a stereotaxic frame mounted on a tripod to orient the visual axis perpendicular to a large tangent screen. Photographs were taken of both retinae and landmarks were projected onto a tangent screen with a fundus camera to pinpoint their eccentricity. Retinal magnification factor was 161 μm per degree in the central 24°. One eye was then enucleated under sterile conditions. Buprenorphine (0.03 mg/kg) was administered for 48 hours after surgery for analgesia. After a survival time of at least 10 days, the animal was killed with sodium pentobarbital (150 mg/kg) and perfused with 1% paraformaldehyde. Flatmounts were cut at 30 to 40 μm, air-dried on slides, reacted for CO, and montaged with Photoshop 6.0.

28. Entrance pupil size was measured by photography with a 100-mm macro-lens in five squirrel monkeys aged 1 week; it was 1.9 ± 0.03 mm (SEM), with a range of 1.7 to 2.0 mm. This value was used for exit pupil size, because for small pupils, the difference between entrance and exit pupil size is negligible. Distance from pupil to retina was measured in three newborn squirrel monkeys with A-mode ultrasound; it was 8.4 ± 0.12 mm (SEM). Adult retinae were sectioned at 1 μm in Epon-Araldite and the lumen diameter of identified blood vessels was measured. Distance from retinal vessel to photoreceptors was also measured in these sections. Correction was made for retinal growth and tissue shrinkage.
29. About 50 to 100 correspondence points were used to warp the nasal retina onto the cortex, using Elastic Reality 3.0 (www.avid.com). No angioscotoma representations were present centrally, so points were obtained from Cowey's microelectrode mapping of the central 4° (*30*). Linear cortical magnification factor along polar rays (M_p) and along eccentricity rings (M_e) were calculated independently: $M_p = 9.5\,(0.95 + E)^{-1.03}$ and $M_e = 188\,(6.45 + E)^{-1.85}$, where E is eccentricity.

A Smartphone App Reveals Erratic Diurnal Eating Patterns in Humans that Can Be Modulated for Health Benefits

Graphical Abstract

Highlights

- The daily eating pattern in healthy adults is highly variable from day to day
- More than half of the adults eat for 15 hr or longer every day
- Sleep duration parallels the fasting duration
- Reducing the daily eating duration can contribute to weight loss

Authors

In Brief

Gill et al. developed a smartphone app to monitor food intake in healthy adults, revealing frequent and erratic daily eating patterns rather than the self-reported three daily meals, leading to "metabolic jetlag." In a pilot study, overweight individuals using the app to eat for only 10–11 hr/day experienced sustained weight loss.

SUMMARY

A diurnal rhythm of eating-fasting promotes health, but the eating pattern of humans is rarely assessed. Using a mobile app, we monitored ingestion events in healthy adults with no shift-work for several days. Most subjects ate frequently and erratically throughout wakeful hours, and overnight fasting duration paralleled time in bed. There was a bias toward eating late, with an estimated <25% of calories being consumed before noon and >35% after 6 p.m. "Metabolic jetlag" resulting from weekday/weekend variation in eating pattern akin to travel across time zones was prevalent. The daily intake duration (95% interval) exceeded 14.75 hr for half of the cohort. When overweight individuals with >14 hr eating duration ate for only 10–11 hr daily for 16 weeks assisted by a data visualization (raster plot of dietary intake pattern, "feedogram") that we developed, they reduced body weight, reported being energetic, and improved sleep. Benefits persisted for a year.

INTRODUCTION

Life on earth has evolved in the context of a 24 hr periodicity in environmental conditions and a dependent daily rhythm in food availability and predator avoidance. Consequently, organisms have evolved endogenous circadian oscillators that allow them to anticipate and prepare for activity, sleep, and food intake at a specific time of the day. Both food ingestion and fasting can alter the metabolic state. Therefore, molecular responses to feeding and fasting exhibit temporal dynamics with a 24 hr period. The circadian oscillator and time of feeding act together to drive daily rhythms in gene expression and protein function such that the anticipation of and responses to feeding events are properly timed (Adamovich et al., 2014; Vollmers et al., 2009) every day. Genetic disruption of circadian rhythms in experimental animals and behavioral disruption of circadian rhythm among shift workers likely perturbs such temporal regulation and predisposes to metabolic diseases (Asher and Schibler, 2011). Frequent caloric intake in animal models of diet-induced obesity also dampens molecular circadian rhythms (Kohsaka et al., 2007). Conversely, recent studies in both nocturnal (mice) and diurnal (*Drosophila melanogaster*) model organisms have demonstrated that restricting the time of caloric intake to a window of 8–12 hr without altering the quantity or quality of diet can impart pleiotropic physiological benefits (Chaix et al., 2014; Gill et al., 2015; Hatori et al., 2012; Sherman et al., 2012; Zarrinpar et al., 2014). Such time-restricted feeding (TRF) supports a robust circadian rhythm and is associated with reduced adiposity, elevated lean mass, longer sleep duration, increased endurance, reduced systemic inflammation, decelerated cardiac aging, gut homeostasis, and improvement in other clinically relevant biomarkers.

Despite these observed benefits in model organisms, the applicability of TRF for human health has remained unknown, because the temporal aspect of human eating pattern is rarely measured. A lack of methods and parameters to describe the daily eating pattern in humans makes it difficult to ascertain whether eating events in humans are spread over a long enough segment of the 24 hr day such that there is an opportunity to reduce this duration. Furthermore, differences between metabolic properties of humans and those of small model organisms make it difficult to predict whether an 8–12 hr eating window will impart physiological benefits in humans. Nevertheless, accumulating data indicate that the temporal aspect of food intake, in addition to total caloric intake, can be an important determinant of predisposition to chronic diseases (Mattson et al., 2014), which now are the predominant cause of morbidity and mortality in developed nations (Bauer et al., 2014). Therefore, the objective longitudinal assessment of the content and the daily temporal pattern of human nutrition could have a major public health impact in terms of finding at-risk individuals for chronic disease and subsequent corrective action through lifestyle interventions.

Current methods to monitor human nutrition are subjective (such as questionnaires), remove subjects from their usual spatiotemporal niche (e.g., in-lab videography with limited food choices), or provide negative feedback that interferes with subjects' behavior (food diaries). Moreover, these methods gather information on the quantity and quality of nutrition and generally do not seek information regarding the time at which the food or beverage was consumed. The availability of smartphones presents an opportunity to objectively monitor human nutrition along with the advantage of complete control over feedback. The wide-ranging adoption of smartphones across age, gender, and socioeconomic segments can be leveraged to study behaviors of free-living individuals at scale in heterogeneous populations.

In this study, we developed and used a smartphone-based monitoring method with minimal feedback to collect the natural daily eating pattern of free-living healthy adults. In contrast to the conventional wisdom that modern humans eat 3 meals a day within a 12 hr interval, eating pattern was found to be largely erratic and differing between weekdays and weekends. In a pilot feasibility study, we tested whether reducing the eating interval to 10–11 hr without an overt attempt to change nutrition could lead to weight loss in healthy overweight individuals. Overall, the results presented here show that a large segment of the human adult population displays an erratic daily rhythm of eating-fasting, which can be manipulated to obtain desirable health benefits.

RESULTS AND DISCUSSION

A Smartphone App to Monitor Daily Eating Patterns

We built a smartphone software application (“app”) to longitudinally monitor the daily temporal pattern of caloric intake in free-living humans. To record an ingestive event, the participants used the camera function of the smartphone to take a picture of the food or beverage. Food pictures taken in the JPEG format were downscaled to 1/10 their original size on the device itself to reduce network data usage. Participants also had the option for textual entries to substitute for food/drink pictures when picture taking was difficult or when subjects forgot to log their picture entries. Immediately after data logging, the food picture and text entries along with timestamp and geolocation were immediately transferred to a server. Upon confirmation of successful data transfer, the data and the associated metadata (i.e., the timestamp and geolocation) were erased from the subject’s device, eliminating the possibility for the “feedback effect” of prior-recorded information upon present behavior.

We made use of push notifications as an orthogonal measurement technique for assessing the time of diet intake. These push notifications were manually triggered at a random time of the day, during the stated wakeful period of the subject and numbered 1–2 per day. The specific push notification query presented to the subject was dependent on the time when he/she responds to it, not when it was originally dispatched from the server. The push notification presented a query on the user’s device inquiring whether they ate/drank anything in the past 30 min. Subjects had to push a “Yes” or “No” button displayed on their screen, and their responses were recorded on the server. From such responses to push notifications sent at a random time during wakeful hours, we estimated the false negative rate (i.e., when the subject consumed food/beverage/water, but forgot to log the event) for our methodology to be 10.34%.

We monitored healthy, non-shift-worker adult males and females (Figures 1A and 1B, Table S1) for 3 weeks. After meeting the inclusion and exclusion criteria (Table S2) and signing an informed consent document during an office visit, subjects used the custom mobile application (Salk Metabolic App) installed on their smartphone to take pictures of every food, beverage, or water item they consumed, irrespective of volume or calorie, just prior to consumption (Figures S1 and S2). Appending a textual annotation describing the amount and the item(s) consumed to the pictures was optional.

The food pictures or occasional text entries (2.1% of all events) were further annotated by looking up the reference nutrition values from Calorie King or FNDDS (Six et al., 2011). Out of the 26,676 events recorded, 22% (5846) were water, 28% (7420) consisted of pre-packaged items with readily accessible nutrition information, and 50% (13,410) were mixed meals with multiple items. We hypothesized that the reported caloric intake should at least meet the resting energy expenditure or maintenance caloric (MC) intake (Roza and Shizgal, 1984). The average daily estimated caloric intake for the group (mean 1,947 kcal; 95% CI: 1,917–1,977) was more than their respective maintenance caloric intake (mean 1.233-fold over MC; 95% CI: 1.214–1.251). From push notifications, we had measured a false negative rate or underreporting of food/beverage/water to be 10.34%. Therefore, the actual caloric intake was likely little higher. The extra caloric intake likely accounts for activity above resting metabolism. There was no significant change in body weight during the 3-week reporting period (Table S1), indicating any potential feedback effect on weight loss due to recording food intake was absent.

Daily Eating Patterns in Humans

The timestamp of every ingestion event allowed analyses of the temporal aspect of eating. Aggregate data from 3 weeks of monitoring was used to assess eating pattern of the cohort. Caloric (i.e., >5 kcal) events populated a large segment of the 24 hr day (Figures 1C and 1D), and there were only 5 hr between 1–6 a.m. when the number of events/hr were <1% of total events (Figure 2A). The fraction of events with estimated energy content >5 kcal also reached its nadir (Figure 2B) in that interval. Because at the population level human digital activity reaches the trough between 2 and 4 a.m. (Golder and Macy, 2011), none of the subjects were self-reported shift-workers, and the reporting trough was close to 4 a.m. (Figures 2A and 2B), we considered 4 a.m. as the onset of “metabolic day” (i.e., events between 00:00:00 and 03:59:59 hr were included in the previous calendar day).

Surprisingly, in contrast to the self-reported 3 meals/day structure of meals from most of the participants, a breakfast-lunch-dinner temporal pattern was largely absent (Figure 2C). At the individual level, the number of events/day showed wide variation ranging from 4.22 ± 0.1 (mean + SEM) for the bottom decile to 15.52 ± 0.34 for the top decile, of which 3.33 ± 0.07 and 10.55 ± 0.24, respectively, were caloric events (Figure 2D).

From a subset of events that marked the beginning and end of an eating report (i.e., pictures of food at the start and of leftovers at the end of the meal), we calculated the average meal duration to be 14 min 36 s. Therefore, “events” from an individual with a <15 min inter-event interval were combined into one “meal.” At the group level, 25% of all meals were within 1 hr 25 min of another meal, and the median inter-meal interval was 3 hr 6 min. Only 25% of the meals occurred after >6 hr 41 min of fasting (Figure 2E).

The fraction of total calories consumed (starting at 4 a.m.) showed that less than 25% of caloric intake occurs before noon (Figure 2F). The percentages of total calories consumed after 6 p.m., 9 p.m., and 11 p.m. (and before 4 a.m. of the next day) were 37.5%, 12.2%, and 3.9%, respectively (Figure 2F). After adjusting for maintenance calories (MC) for each individual (Roza and Shizgal, 1984), the average cumulative percentage of

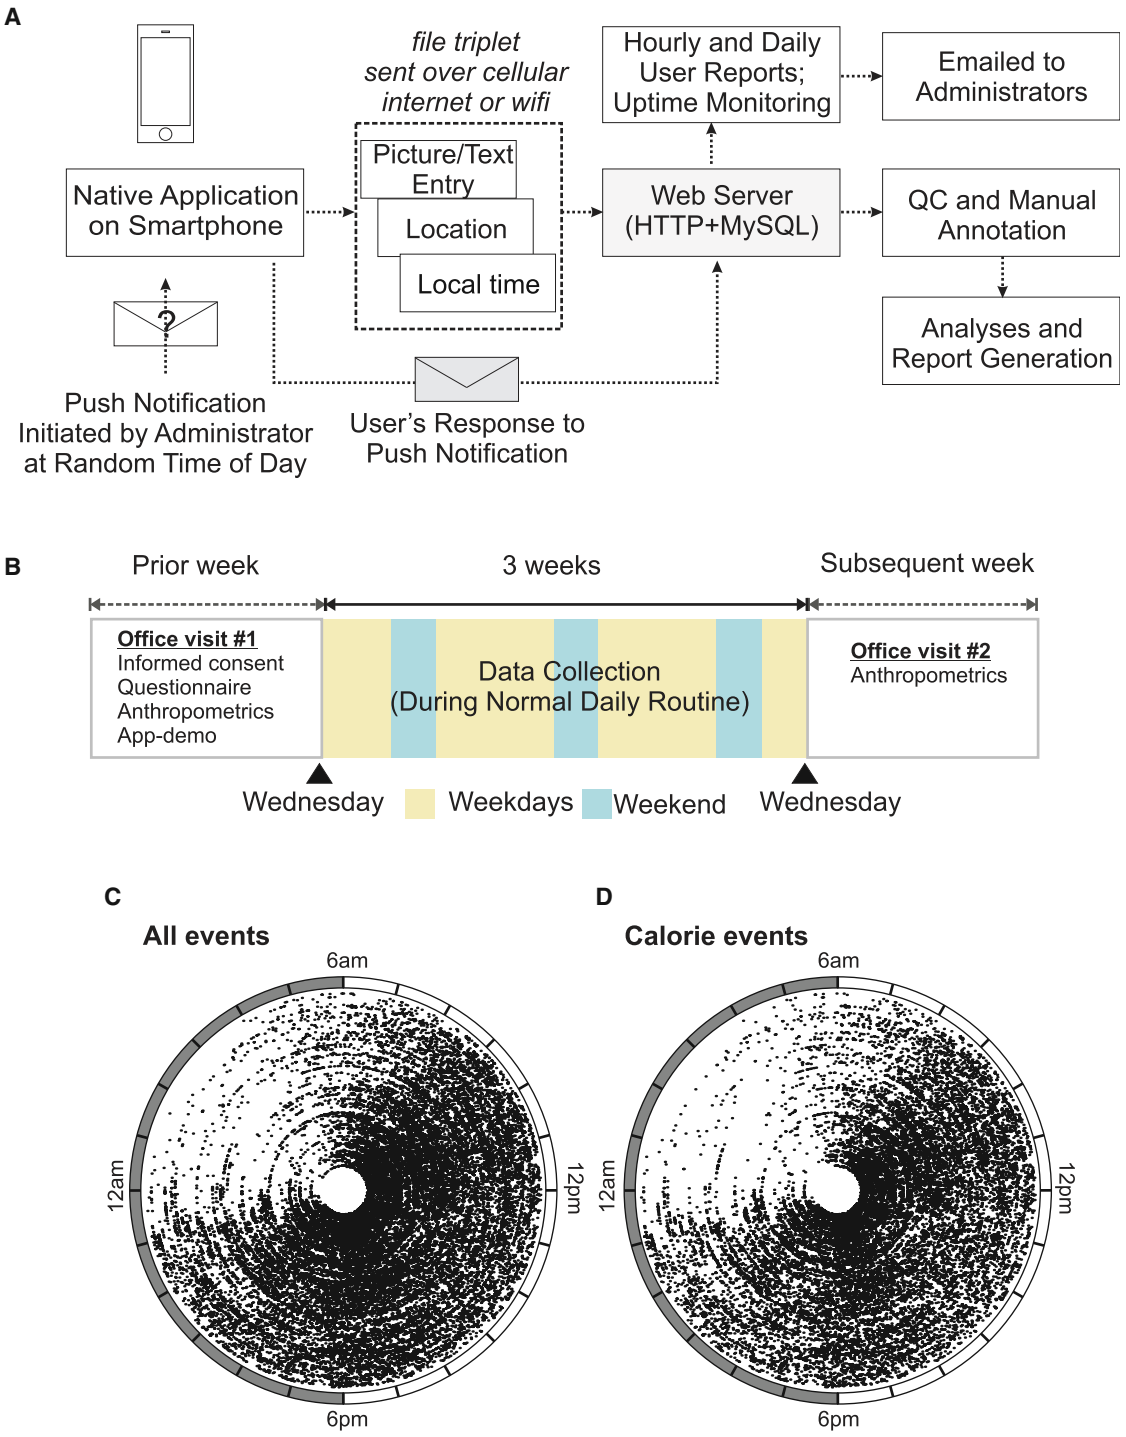

Figure 1. A Scalable Method to Monitor Daily Patterns of Dietary Intake in Humans

(A and B) Schematic (A) of the smartphone-based approach to monitor human eating pattern used to monitor all ingestion events for a 3-week period in healthy adults (B).

(C and D) Polar plot of all (C) or calorie-containing ($\geq$5 kcal) (D) ingestion events of each individual plotted against the time of day (radial axis) in each concentric circle. Data from 156 individuals are shown.

MC ingested over diurnal time showed the average time by which 50%, 70%, 90%, and 100% of MC were consumed to be 3:32 p.m., 5:04 p.m., 6:11 p.m., and 6:36 p.m., respectively (see Figure 2G for median values). In summary, there is a systematic bias toward consuming a larger portion of the daily caloric intake toward the late afternoon and evening hours. At the cohort

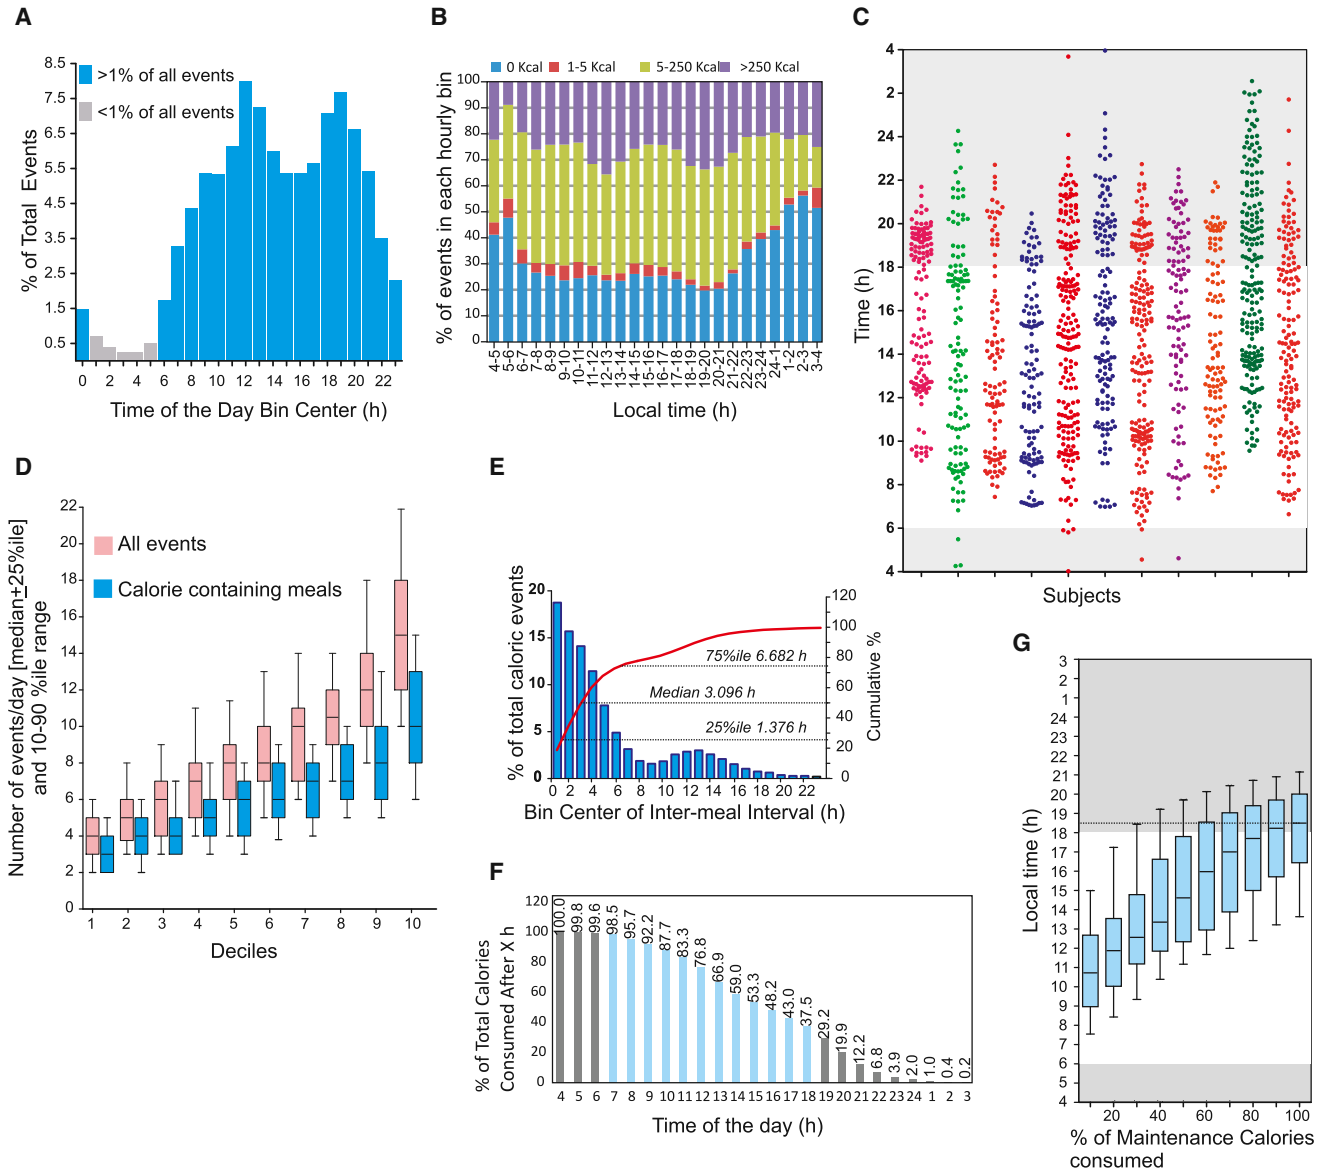

Figure 2. Human Eating Lacks 3-Meals-a-Day Structure

(A) Percentage of all ingestion events in 1 hr bin shows the nadir at 4 a.m.

(B) The fraction of events with <5 kcal also reaches its peak at 4 a.m. Therefore, we considered 4 a.m. (instead of midnight) as the beginning of the metabolic day.

(C) Representative scatter plot of ingestion events of 11 subjects during the observation period shows the lack of clustering of events into three principal bins for most individuals and a large variation in the total number of events.

(D) Number of ingestion events/day in all subjects binned into 10 deciles shows a wide distribution of number of total and calorie-containing events every day.

(E) Frequency distribution and cumulative frequency of inter-meal interval for the entire cohort.

(F) Percentage of calories remaining to be consumed in each hourly bin shows that >75% of all calories are consumed after midday.

(G) Time (median + 25%–50% range and 10%–90% interval) at which percentage of maintenance calories are consumed in 10% increments is shown.

level, in general, food consumed after 6:36 p.m. exceeded the maintenance calories requirement.

Eating Pattern Relative to Wakeful Hours

To compare the eating pattern with diurnal activity period, wrist actigraphy (Blood et al., 1997) data were collected from 47 randomly selected participants using a CamNTech Motionwatch 8, a device that measured both activity and light. A nighttime drop in activity and an absence of light was scored as time in bed. Integration of activity, light, and ingestion events allowed analyses of eating time relative to activity period (Figure 3A). The average time of activity onset and of time to bed showed large variation even among this non-shift worker cohort (Figure 3B). The median time interval between daily activity onset and first caloric intake was 1 hr 18 min, while the median time between the last caloric intake and going to bed was 2 hr 22 min

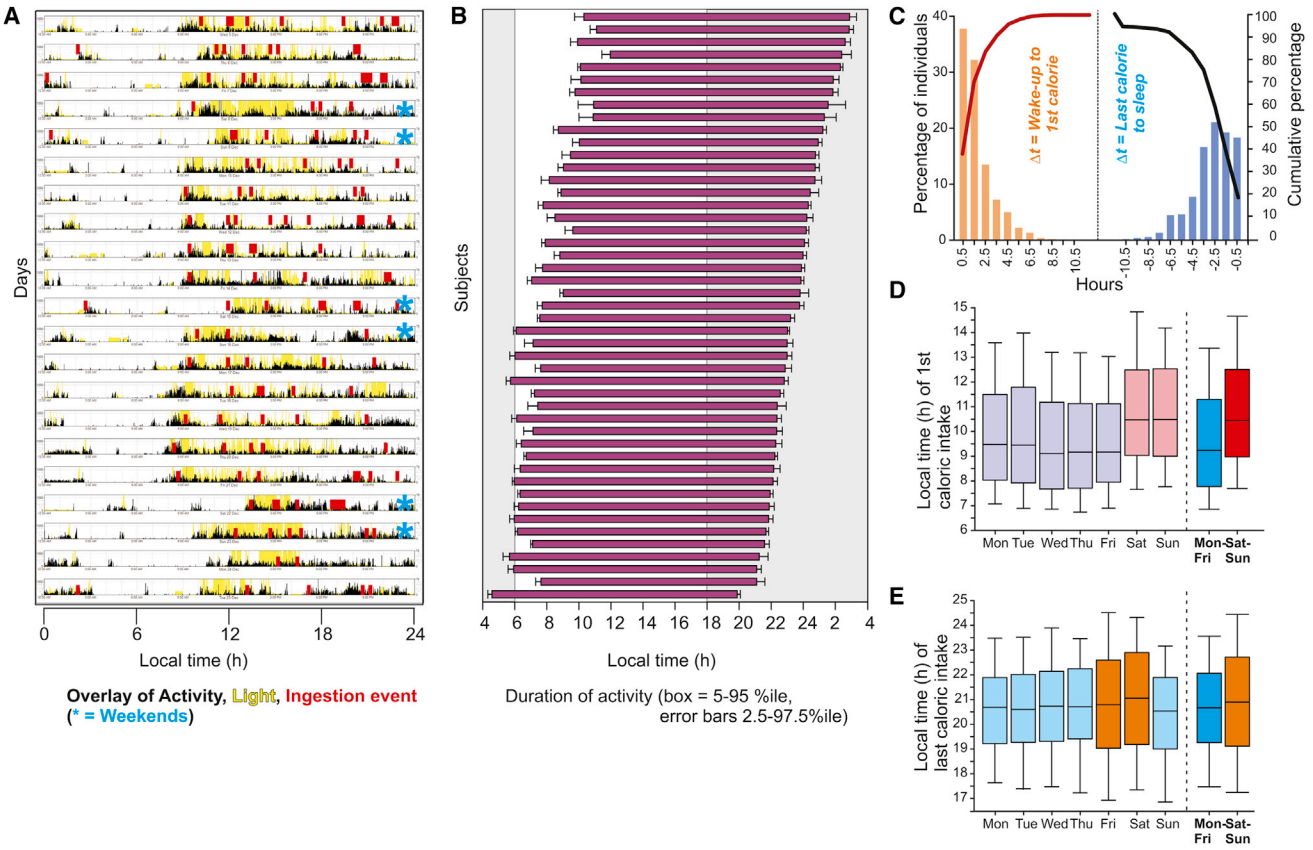

Figure 3. Activity and Eating Duration in Adult Humans

(A) Representative actogram and light exposure pattern (from a wrist-worn device) of a subject for 3 weeks overlaid with ingestion events (from smartphone app) show that the latter occur erratically throughout the active period.

(B) Wakeful activity duration in a subset of the subjects is shown. Each horizontal bar shows the interval between average wake up and bedtime (+SEM, up to 21 days of monitoring).

(C) Time interval between waking up and the first caloric ingestion or the last caloric ingestion and going to bed. Bars (orange and blue, y axis) indicate the percent of the individuals for whom actigraphy was performed with the indicated number of hours (x axis, 1 hr bins) from waking up to the first caloric intake or from the last caloric intake to sleep. Cumulative percentages (secondary y axis) are shown in color-matched lines.

(D and E) Median time of first (D) and last (E) caloric event of all individuals on different days of the week. Median (25%–75% interval in box, 10%–90% interval in lines) local time is shown.

(Figure 3C). Therefore, the total overnight fasting duration paralleled the time of inactivity (sleep) at night.

The day-to-day variation in the time of first or last caloric intake was spread over a few hours (Figure S3). Feeding after several hours of fasting is known to affect neuroendocrine metabolic pathways and adjust the phase of the circadian clock in peripheral organs (Vollmers et al., 2009) so that physiological state transitions from the fasting to the fed state. Changes in the sleep-wake cycle between social/work days and free/weekend days is similar to the circadian desynchrony arising from jet travel between time zones and is called social jetlag (Roenneberg et al., 2012). By analogy, we postulated that the variation in breakfast time between working/week days and free/weekend days likely affects the peripheral clocks in metabolic organs, causing metabolic desynchrony or "metabolic jetlag." The median breakfast (i.e., the first caloric intake event) time for the entire population changed on Saturday and Sunday (Figures 3D and S3), so we considered those two days as the "metabolic weekend." The time of last caloric intake did not significantly change in any of the days, but the variability was relatively large on Friday and Saturday (Figures 3E and S3). At the population level, the mean times of first caloric intake during weekdays and weekend were 9:21 a.m. (95% CI: 9:15–9:27 a.m.) and 10:26 a.m. (95% CI:10:15–10:37 a.m.), respectively. Delaying breakfast was more common than advancing it, with 40% of the subjects delaying breakfast by 1 hr or longer and 25% by 2.18 hr, while only 7% advanced their breakfast time by >1 hr. The time of last caloric intake was more variable than breakfast. The average last caloric intake time was advanced by >1 hr in 17%, while only 15% delayed the time of last caloric intake by >1 hr on the weekend.

Eating Duration and Eating Pattern

Having observed a large variance in the first and last caloric intake (Figure S3) and the absence of a clear 3 meals/day eating pattern (Figures 2C and 2D) for most subjects, a potentially better description of an individual's eating pattern could be the daily duration of caloric intake. Because food intake triggers postprandial changes in neuroendocrine state that can take minutes

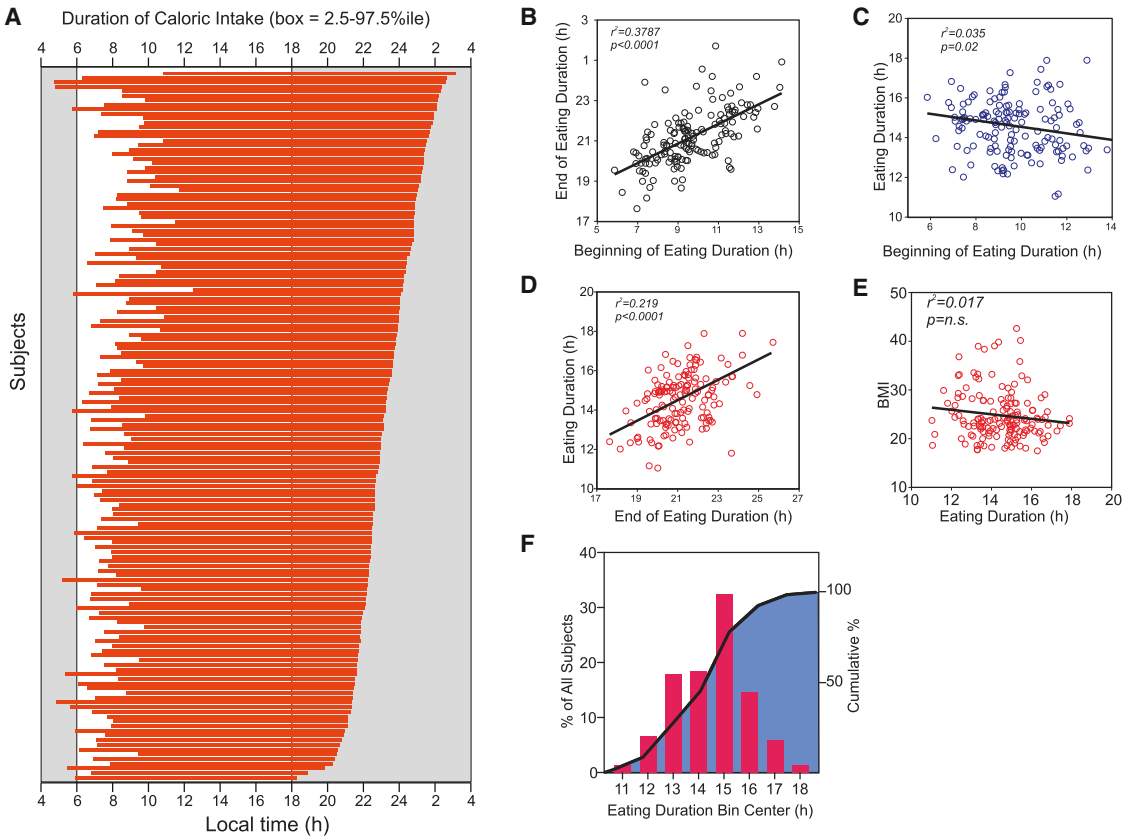

Figure 4. Daily Duration of Caloric Intake

(A) Eating duration of all individuals is shown in the order of late (top) to early (bottom) nighttime fasting onset time.

(B) The time of last caloric intake weakly positively correlates with the time of first caloric intake.

(C and D) The daily duration of eating does not correlate with the time of first caloric intake (C) but weakly positively correlates with the time of the last caloric intake (D).

(E and F) The subjects' daily eating duration does not correlate with their BMI (kg/m^2) (E), frequency distribution (red bars), and cumulative percentage (black line and blue filled area) of eating duration (hours) (F).

to hours to return to resting or fasting state, eating too often could clamp the physiological state between frequent meals to the post-prandial state. Therefore, we defined the daily eating duration as the time interval (4 a.m. onward) that contained 95% (2.5–97.5 percentile) of all intake events during the monitoring period (Figure 4A). This approach for arriving at the eating duration from aggregate data over several days is tolerant of occasional non-reporting of some random eating events. Breakfast time weakly positively correlated with the last caloric intake (r^2 = 0.379), so that individuals with earlier breakfast also had their last caloric intake earlier in the evening (Figure 4B). The eating duration better correlated with the time of last caloric intake (r^2 = 0.215) than with the time of breakfast (r^2 = 0.035) (Figures 4C and 4D) or with BMI (r^2 = 0.017) (Figure 4E). The median daily eating duration was 14 hr 45 min, and only 9.7% of the subjects had a daily eating duration <12 hr (Figure 4F) long. The weak correlation (r^2 = 0.017) between the eating duration and BMI could be due to the limited sample size, the heterogeneity of the participants in terms of gender and age, and the fact that the eating pattern recorded in the monitoring period is a short-term snapshot of a person's long-term diet-related behaviors.

Restricting Eating Duration Reduces Body Weight

Many factors, including nutrition quality, quantity, physical activity, and genetics contribute to obesity. Although we did not find a simple correlation between BMI and eating duration, we wanted to test whether longer eating duration and erratic eating pattern are contributing factors in subjects with co-occurrence of >25 BMI and >14 hr eating duration. We tested if reducing the eating duration and metabolic jetlag associated with weekday/weekend differences in a subset of individuals would lead to reduction in body weight. We recruited 8 individuals with >14 hr eating duration for a 16-week pilot intervention study, such that each individual's own baseline data served as the control (Figure 5A) condition. Individualized "feedogram" graphics representing a temporal raster plot of ingestion events in successive days were constructed (Figure 5B). After obtaining informed consent for intervention, the participants were provided data regarding their eating pattern accrued in the 3-week baseline period (95% eating duration, variance in first and last caloric intake, and weekday-weekend metabolic jetlag) and were shown their own baseline "feedogram" prior to the intervention. Because in rodents a daily eating period of up to 12 hr improves metabolic fitness (Chaix et al., 2014),

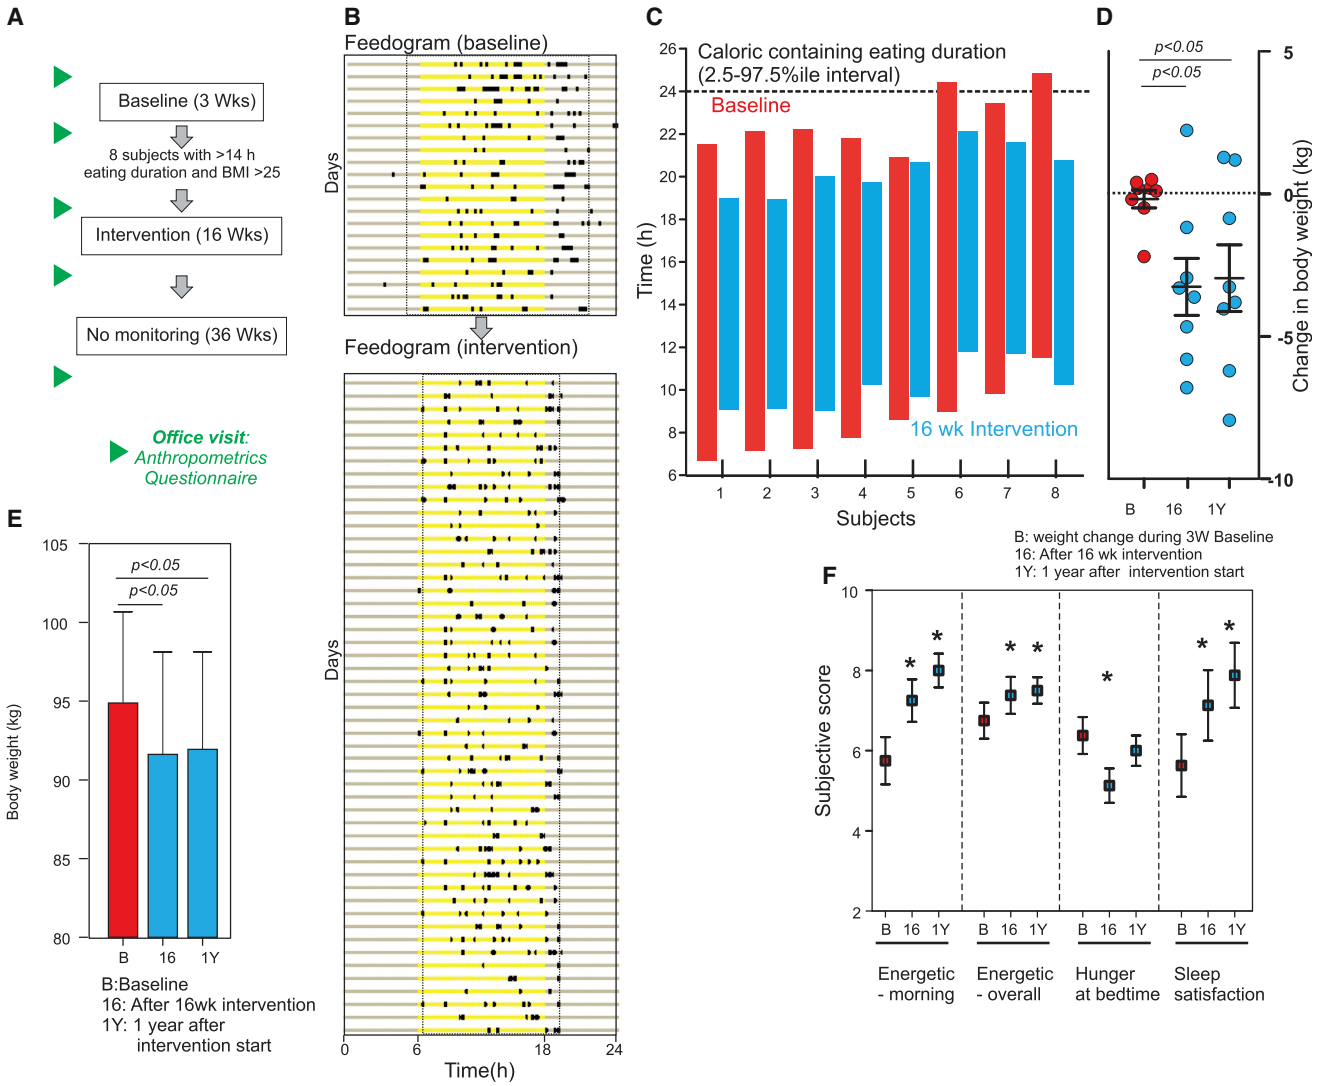

Figure 5. Improved Eating Pattern Reduces Body Weight in Healthy Overweight Individuals

(A) Schematic of the study design to test the effect of eating pattern on body weight.

(B) Representative "feedogram" of a participant during baseline and during intervention. The times of ingestion events are denoted as prominent black rectangles along the 24 hr day represented in each horizontal line (x axis). Yellow represents the time between 6 a.m. and 6 p.m. Eating duration during baseline and intervention is shown as broken lines.

(C) The daily eating duration of each individual during baseline (red) and intervention (blue) plotted against the local time (y axis).

(D) Scatter plot and average (±SEM) change in body weight in 8 participants during 3 weeks of baseline monitoring, after 16 weeks of intervention and after 1 year.

(E) Average (+SEM) body weight at the end of 3 weeks of baseline, after 16 weeks of monitored intervention and at 1 year.

(F) Average (+SEM) of subjective measures of energy level, hunger, and sleep in subjects. These subjective measures were assessed on a scale of 1–10, with 10 being the preferred (healthier) end of the range. Higher numbers thus indicated healthier values for the quantity, i.e., more energetic, less hunger at bedtime, and more sleep satisfaction. *$p < 0.05$, t test.

the participants were requested to reduce their caloric-containing eating duration to a self-selected window of 10–12 hr and to consistently follow this duration during both weekdays and weekends so that the metabolic jetlag could be minimized. No overt suggestion concerning nutrition quality, quantity, or caloric content was provided. The individuals continued logging their food pictures using the same app as used in the baseline period for the next 16 weeks and also received a weekly summary of their feedograms and daily eating duration.

All subjects reduced their eating duration (average reduction: 4 hr 35 min; 95% CI: 3 hr 30 min–5 hr 40 min; $p < 0.001$), and their weekday/weekend metabolic jetlag was also reduced to <1 hr (Figures 5B and 5C). The participants showed a reduction in total body weight (average loss 3.27 kg; 95% CI: 0.9081–5.624 kg) and, accordingly, excess body weight (Figures 5D and 5E, Table S3) and BMI (average reduction 1.15 kg/m^2; 95% CI: 0.3247–1.980 kg/m^2). In a subjective self-assessment of sleep satisfaction, hunger at bedtime, and energy level

(in the mornings, and overall over the past few days), statistically significant improvement was observed (Figure 5F). All participants voluntarily expressed an interest in continuing unsupervised with the 10–11 hr time-restricted eating regimen after the conclusion of the 16-week supervised intervention. After 36 weeks (1 year since the intervention began), the participants maintained weight loss and sleep improvement and felt more energetic (Figures 5D–5F, Table S3).

Although the participants were not overtly asked to change nutrition quality or quantity, reducing the eating duration led to reduced estimated caloric intake. Unlike mice, where reducing the eating duration to ~10 hr does not alter total caloric intake (Hatori et al., 2012), our human intervention cohort reduced the estimated daily caloric intake (average reduction 20.26%; 95% CI 4.92%–35.6%; paired t test $p < 0.05$). Humans consume heterogeneous food types in a time-of-the-day-dependent manner (Figure S4), e.g., coffee is almost always consumed in mornings, while alcohol at night. As a result, during the intervention, it was not the case that items that would have otherwise (in the baseline period) been consumed in the designated 14 hr nighttime fasting hours had been moved to the self-selected 10 hr feeding period during the intervention. Instead, the person would simply not consume such an item rather than consume it at the wrong time of day. This could be one potential explanation for the reduction in caloric intake.

Discussion

Collecting human nutrition information in the free-living condition has been a persistent challenge. Recording dietary intake using text entries, selecting from a large library of food items, and specifying the portion size is a ubiquitous feature found in most nutrition apps. Although such apps improve adherence relative to the traditional diary log (Carter et al., 2013), data logging can be cumbersome for mixed meals, and consequently, users may not bother to log small snacks. Furthermore, portion size reporting can be subjective. By adopting an approach centered on food pictures with an optional user-side annotation together with infrequent, but randomly timed, push notifications, we reduced the barrier to data recording. Server side annotation of the picture metadata ensured uniformity across the cohort. Supervised crowd-sourced annotation can make this approach scalable to large cohorts.

By overlaying the daily patterns of food and beverage intake, activity-rest, and light exposure, we could uncover relationships among them (Figures 3A–3C). Data integration from multiple such longitudinal data streams has immense promise for disease prognosis. Although the subjects did not have any chronic medical conditions, they also logged their consumption of vitamins, supplements, and occasional over-the-counter medications for minor ailments, thus offering a temporal pattern of drug and supplement use (Figure S4). Greater than 50% of the mammalian transcriptome exhibits diurnal rhythms in a tissue-specific manner (Zhang et al., 2014), the gut microbiome shows daily rhythms (Thaiss et al., 2014), the timing of food affects these rhythms in peripheral organs (Vollmers et al., 2009), and the targets of a large number of FDA approved drugs show circadian expression (Zhang et al., 2014). Therefore, monitoring the timing of drug intake relative to the sleep-wake or feeding-fasting cycle can have a significant impact on disease prognosis and unraveling interactions among food, sleep, and drugs in free-living individuals.

Formally, our work introduces a method and the critical defining parameters for describing the diurnal and longer-term temporal characteristics of nutrition in humans. By creating a scalable method to longitudinally monitor human nutrition in an evidence-based manner, we discovered that the daily eating pattern even among healthy non-shift young workers is highly variable from day to day. For more than half of the participants in the baseline monitoring study, the eating pattern is erratic, and energy intake events span over a large fraction of a 24 hr day, with a relatively short fasting period (Figure 4). Although the first caloric intake after leaving the bed happened within 1 hr 18 min (median value) (Figure 3C), less than 25% of the daily caloric intake occurred before noon, while 37.5% was consumed after 6 p.m. (Figure 2F). This suggests that breakfast is relatively small in terms of energetic input and that major caloric intake is delayed until later in the afternoon or evening in this set of relatively young (Table S1) non-shift-worker subjects. To address the universality of our observations concerning eating patterns, this method may be extended to a larger population spread over different geographical regions, work schedules (e.g., shift-workers, retired individuals, nurses, pilots), age groups, and/or cultures. It would also be useful to describe the diurnal patterns of caloric intake in humans that do not have a modern lifestyle influenced by electricity, such as hunter-gather societies.

Individuals in our study largely ate throughout the wakeful hours (Figure 3). Consequently, sleep duration and quality largely dictated the eating pattern. Furthermore, since the sleep pattern changes between weekdays (workdays) and weekends, leading to social jetlag (Roenneberg et al., 2012; Wittmann et al., 2006), the breakfast time also changes between weekdays and weekends. These changes in breakfast time are analogous to a person traveling across time zones every weekend and can be described as metabolic jetlag. The intricate connection we observed between sleep and overnight fasting duration suggests that the observed relationship between a short sleep duration and predisposition to metabolic diseases (Cappuccio et al., 2011; Copinschi et al., 2014) may be partly explained by the reduced duration of overnight fasting. Similarly, the reported correlation between social jetlag and BMI may also involve metabolic jetlag. The increased daily eating duration likely contributes to increased caloric intake. A change in eating pattern between days (e.g., weekday versus weekend) can affect time-of-day/night-specific changes in food intake from specific food groups (Figure S4). Therefore, one mode by which reduced sleep duration contributes to the increased risk for metabolic diseases could be the increased daily eating duration and associated changes in caloric intake and nutrition quality.

We did not find a simple positive correlation between the daily eating duration and BMI in our cohort. This may be for several reasons, including a limited sample size, heterogeneity of the cohort, and a likely scenario that individuals with long eating duration may also have more physical activity. Nevertheless, reducing the temporal eating period in a feasibility study imparted measurable benefits of clinically relevant magnitude in terms of body weight reduction and sleep improvement without increasing the subjective sense of hunger. This relatively large

effect on body weight reduction, even in the small intervention cohort, implies that the benefits might result from multiple changes: restoration of the diurnal rhythm of feeding/fasting, reduction of the weekday/weekend metabolic jetlag, and a reduction in the daily caloric intake. Some benefits of TRF might arise from caloric reduction (CR). At the same time, we cannot rule out the possibility that some benefits of CR in vertebrates including humans might be from TRF, as most CR studies involve caloric intake within a defined time frame. Nevertheless, if time restriction under free-living condition inadvertently leads to caloric reduction, TRF as a method to reduce caloric intake is a more attractive option, as individuals, caregivers, case managers, physicians, and scientists do not have to adopt expensive and laborious methods to accurately track caloric count. Hence, irrespective of mechanism, time restriction offers an effective approach to improve health.

While the relative contribution of daily eating pattern, calories, and nutrition quality to multifaceted health improvement in humans should be examined in detail in future studies, our results highlight that suitable manipulation of the diurnal temporal pattern of caloric intake is a feasible therapeutic approach for improving human health in the free-living condition, in spite of the vast variety of food and beverage types consumed by the average person from day to day. This opens up the possibility for utilizing this strategy by itself or in combination with existing approaches for health improvement.

EXPERIMENTAL PROCEDURES

This study was approved by the IRB of the Salk Institute. Participants were recruited during 2012–2013 through a newspaper advertisement, paper flyers, and online advertisements. Inclusion and exclusion criteria were determined by an online questionnaire and an in-person interview. All subjects provided written informed consent during the first office visit and were asked to record all of their food, beverage, and water intake using the smartphone app. Subjects' height and weight were measured using a calibrated scale and tape measure at the beginning and end of the 3-week baseline period. Participants were nominally compensated for their time and effort.

For the baseline study aimed at observing eating patterns in free-living adults, data were collected from a Tuesday/Wednesday midnight to another Tuesday/Wednesday midnight 21 days later. Subjects received instructions to record every item consumed (food, drink, water) regardless of its size using the app on their smartphone. The leftovers from items that were not completely consumed were to be recorded again, but described as such in the annotation. Days with fewer than 3 total events (including non-caloric content items) were flagged and verified with the participants for any observed fasting day or whether they forgot to log data.

Subjects from the baseline study with BMI > 25 kg/m^2 and whose intake interval exceeded 14 hr were offered the opportunity to participate in the intervention study. After a detailed presentation on the known benefits of time-restricted feeding in rodents, data on their own eating pattern, and what the intervention study would entail, subjects chose a 10 hr eating interval of their choice and were to limit all non-water intake (including coffee and tea) to that 10 hr interval. Eight subjects entered the study: 5 males (age 34.4 ± 2.9 years, weight 96.7 ± 4.8 kg, BMI 31.77 ± 2.05 kg/m^2), 3 females (age 36.3 ± 4.3 years, weight 91.8 ± 15 kg, BMI 34.91 ± 3.84 kg/m^2; average ± SEM). Ethnicity: 2 Hispanics, 6 non-Hispanic or Latino. Race: 3 Asian, 4 white, 1 more than one race. To identify undiagnosed fasting hypoglycemia, a fasting blood metabolic panel was performed at a certified clinic prior to the intervention study for every subject. During the 16-week-long intervention study, the participants were instructed to log in to a personalized website every week to check their eating duration. Anthropometrics were performed prior to the start of the intervention, just after the completion of the 16-week-long intervention and 1 year after the start of the intervention. As the goal for this feasibility pilot study was to test TRF in healthy overweight subjects with no recent history of fasting blood sugar, cholesterol, and triglycerides outside the reference range, we did not thoroughly investigate clinical biomarkers of metabolic diseases.

Software

The smartphone application was coded in Objective-C. When the application is run for the first time, it generates a unique 20-character alphanumeric code to identify the device as well as records the user's Push Notification Service identifier in a database. Access to the application was restricted to study participants by a one-time username-based validation procedure. Food pictures taken in JPEG format were downscaled to 1/10 their original size on the device itself to reduce data usage. The functionality of each app tab is shown in Figure S1. Push notifications were manually triggered at a random time of the day during the stated wakeful period of the subject and numbered 1–2 per day. The specific push notification-based query presented to the subject is dependent on the time when he/she sees it, not when it was originally initiated from the server. The presented query and the response were recorded on the server.

The Salk Metabolic Study app was available from the Apple App Store during the study period. To limit usage to subjects who provided a written informed consent, the app activation required a randomly generated unique activation key for each participant. Recently, the app was revised, upgraded, and re-written to run on the latest operating systems in iOS and Android devices under the name "myCircadianClock." Under Salk IRB approved study, the app is available to adults living in the U.S. Potential users can visit the website (http://mycircadianclock.mycircadianclock.org/) to review the ongoing study objectives and the consent document. If they consent to participate through electronic consenting, they are sent an activation key to use the app.

Data Annotation and Analysis

Duplicate pictures were first automatically removed by comparing MD5 checksums, which serve as a fingerprint of a file. A second round of de-duplication was performed by manually inspecting the contents of sequentially received food/drink pictures. De-duplicated data were then independently annotated by two researchers for multiple characteristics that describe each item. The items and estimated portion size were also looked up in FNDDS or CalorieKing website for estimated caloric content. A third researcher tallied the annotations and where discrepancies existed; all three individuals conferred and arrived at a consensus description. In recognition of the fact that lifestyles and work schedules are controlled more by conventional time than solar time, the time data shown herein referred to as "local time" incorporate daylight savings time when applicable. In other words, depending on whether daylight savings time was in effect (March–November) or not (November–March), a local time of 9.5 would refer to 9:30 a.m. PDT or 9:30 a.m. PST for an event recorded in California. Polar plots were generated using Mathematica 9 (Wolfram). All other plots and statistical analyses were prepared using Prism 5 (GraphPad Software).

Feedogram

To generate a feedogram raster plot, events were binned into 15 min intervals starting at midnight. Corresponding to each such bin, if an event was recorded in it, the segment in the raster plot was colored black. If no event was present, the segment was colored gray if it was between 6 p.m. and 6 a.m. and yellow otherwise.

SUPPLEMENTAL INFORMATION

Supplemental Information includes four figures and three tables and can be found with this article online at http://dx.doi.org/10.1016/j.cmet.2015.09.005.

AUTHOR CONTRIBUTIONS

Both S.G. and S.P. conceived the idea, designed the experiments, analyzed data, and wrote the manuscript. S.G. wrote the smartphone application and server-side software, recruited subjects, and collected data.

Development of the social brain in adolescence

Sarah-Jayne Blakemore

Institute of Cognitive Neuroscience, University College London, 17 Queen Square, London WC1N 3AR, UK
Email: s.blakemore@ucl.ac.uk

Summary

The brain has evolved to understand and interact with other people. We are increasingly learning more about the neurophysiological basis of social cognition and what is known as the social brain, that is the network of brain regions involved in understanding others. This paper focuses on how the social brain develops during adolescence. Adolescence is a time characterized by change – hormonally, physically, psychologically and socially. Yet until recently this period of life was neglected by cognitive neuroscience. In the past decade, research has shown that the brain develops both structurally and functionally during adolescence. Large-scale structural MRI studies have demonstrated development during adolescence in white matter and grey matter volumes in regions within the social brain. Activity in some of these regions, as measured using fMRI, also shows changes between adolescence and adulthood during social cognition tasks. I will also present evidence that theory of mind usage is still developing late in adolescence. Finally, I will speculate on potential implications of this research for society.

This is the first in a series of three articles on a new clinical concept called violence adapting syndrome

Humans are exquisitely social

Humans are an exquisitely social species. We are constantly reading each other's actions, gestures and faces in terms of underlying mental states and emotions, in an attempt to figure out what other people are thinking and feeling, and what they are about to do next. This is known as theory of mind or mentalising. Developmental psychology research on theory of mind has demonstrated that the ability to understand others' mental states develops over the first four or five years of life. While certain aspects of theory of mind are present in infancy,[1] it is not until around the age of four years that children begin explicitly to understand that someone else can hold a belief that differs from one's own, and which can be false.[2] An understanding of others' mental states plays a critical role in social interaction because it enables us to work out what other people want and what they are about to do next, and to modify our own behaviour accordingly.

The social brain

Over the past 15 years, a large number of independent neuroimaging studies have shown remarkable consistency in identifying the brain regions that are involved in theory of mind or mentalising. These studies have employed a wide range of stimuli including stories, sentences, words, cartoons and animations, each designed to elicit the attribution of mental states (see Amodio and Frith[3] for review). In each case, the mentalising task resulted in the activation of a network of regions including the posterior superior temporal sulcus (pSTS) at the temporo-parietal junction

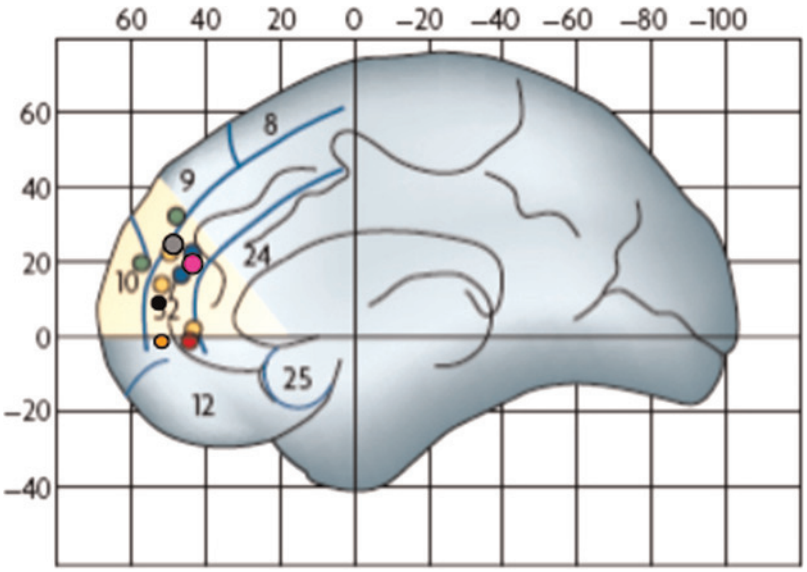
Downloaded from jrs.sagepub.com at GEORGETOWN UNIV MED CTR on May 25, 2015

(TPJ), the temporal poles and the dorsal medial prefrontal cortex (mPFC; see Burnett and Blakemore[4]). The agreement between neuroimaging studies in this area is remarkable and the consistent localisation of activity within a network of regions including the pSTS/TPJ and mPFC, as well as the temporal poles, suggests that these regions are key to the process of mentalising.

Brain lesion studies have consistently demonstrated that the superior temporal lobes[5] and PFC[6] are involved in mentalising, as damage to these brain areas impairs mentalising abilities. Interestingly, one study reported a patient with extensive PFC damage whose mentalising abilities were intact,[7] suggesting that this region is not necessary for mentalising. However, there are other explanations for this surprising and intriguing finding. It is possible that, due to plasticity, this patient used a different neural strategy in mentalising tasks. Alternatively, it is possible that damage to this area at different ages has different consequences for mentalising abilities. The patient described by Bird and colleagues[7] had sustained her PFC lesion at a later age (62 years) than most previously reported patients who show impairments on mentalising tasks. Perhaps mPFC lesions later in life spare mentalising abilities, whereas damage that occurs earlier in life is detrimental. It is possible that mPFC is necessary for the acquisition of mentalising but not essential for later implementation of mentalising. Intriguingly, this is in line with recent data from developmental fMRI studies of mentalising, which suggest that the mPFC contributes differentially to mentalising at different ages.

Development of mentalising during adolescence

There is a rich literature on the development of social cognition in infancy and childhood, pointing to step-wise changes in social cognitive abilities during the first five years of life. However, there has been surprisingly little empirical research on social cognitive development beyond childhood. Only recently have studies focused on development of the social brain beyond early childhood, and these support evidence from social psychology that adolescence represents a period of significant social development. Most researchers in the field use the onset of puberty as the starting point for adolescence. The end of adolescence is harder to define and there are significant cultural variations. However, the end of the teenage years represents a working consensus in Western countries. Adolescence is characterized by psychological changes in terms of identity, self-consciousness and relationships with others. Compared with children, adolescents are more sociable, form more complex and hierarchical peer relationships, and are more sensitive to acceptance and rejection by peers.[8] Although the underlying factors of these social changes are most likely to be multifaceted, one possible cause is development of the social brain.



Recently, a number of fMRI studies have investigated the development during adolescence of the functional brain correlates of mentalising. These studies have used a wide variety of mentalising tasks – involving the spontaneous attribution of mental states to animated shapes, reflecting on one's intentions to carry out certain actions, thinking about the preferences and dispositions of oneself or a fictitious story character, and judging the sincerity or sarcasm of another person's communicative intentions. Despite the variety of mentalising tasks used, these studies of mental state attribution have consistently shown that mPFC cortex activity during mentalising tasks decreases between adolescence and adulthood (Figure 1). Each of these studies compared brain activity in young adolescents and adults while they were performing a task that involved thinking about mental states (see Figure 1 for details of studies). In each of these studies, mPFC activity was greater in the adolescent group than in the adult group during the mentalising task compared to the control task. In addition, there is evidence for differential functional connectivity between mPFC and other parts of the mentalising network across age.[9]

To summarize, a number of developmental neuroimaging studies of social cognition have been carried out by different labs around the world, and there is striking consistency with respect to the direction of change in mPFC activity. It is not yet understood why mPFC activity decreases between adolescence and adulthood during mentalising tasks, but two non-mutually exclusive explanations have been put forward (see Blakemore[10] for details). One possibility is

Figure 1

A section of the dorsal MPFC that is activated in studies of mentalising: Montreal Neurological Institute (MNI) 'y' coordinates range from 30 to 60, and 'z' coordinates range from 0 to 40. Dots indicate voxels of decreasing activity during seven mentalising tasks between late childhood and adulthood.[10,16] The mentalising tasks ranged from understanding irony, which requires separating the literal from the intended meaning of a comment, thinking about one's own intentions, thinking about whether character traits describe oneself or another familiar other, watching animations in which characters appear to have intentions and emotions, and thinking about social emotions such as guilt and embarrassment[9]

that the cognitive strategy for mentalising changes between adolescence and adulthood. A second possibility is that the functional change with age is due to neuroanatomical changes that occur during this period. Decreases in activity are frequently interpreted as being due to developmental reductions in grey matter volume, presumably related to synaptic pruning. However, there is currently no direct way to test the relationship between number of synapses, synaptic activity

Downloaded from jrs.sagepub.com at GEORGETOWN UNIV MED CTR on May 25, 2015

and neural activity as measured by fMRI in humans (see Blakemore[10] for discussion). If the neural substrates for social cognition change during adolescence, what are the consequences for social cognitive behaviour?

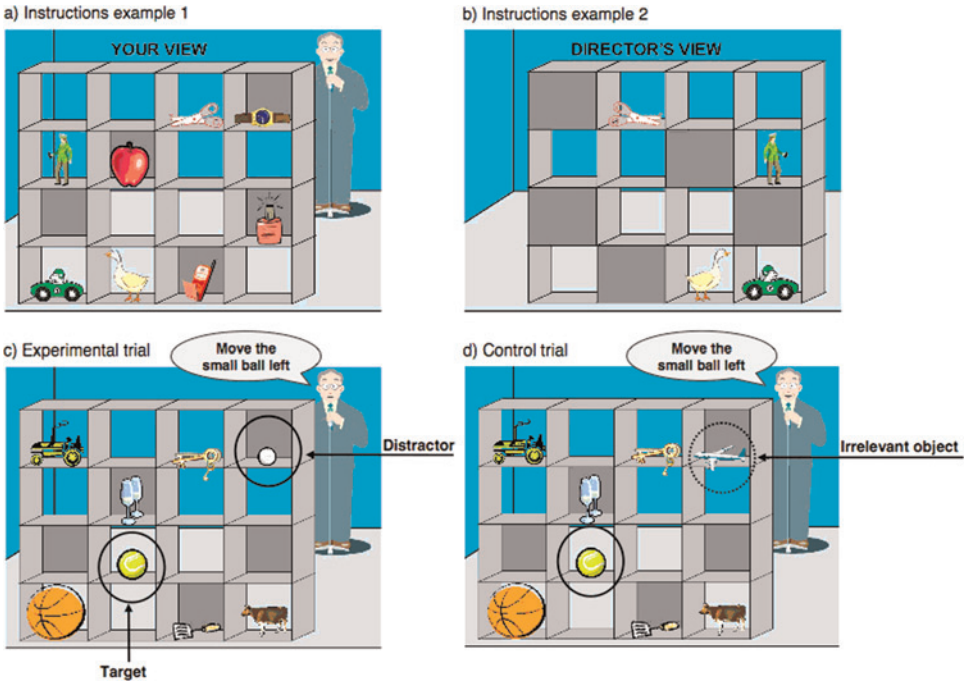
Online mentalising usage is still developing in mid-adolescence

Most developmental studies of social cognition focus on early childhood, possibly because children perform adequately in even quite complex mentalising tasks at around age four. This can be attributed to a lack of suitable paradigms: generally, in order to create a mentalising task that does not elicit ceiling performance in children aged five and older, the linguistic and executive demands of the task must be increased. This renders any age-associated improvement in performance difficult to attribute solely to improved mentalising ability. However, the protracted structural and functional development in adolescence and early adulthood of the brain regions involved in theory of mind might be expected to affect mental state understanding. In addition, evidence from social psychology studies shows substantial changes in social competence and social behaviour during adolescence, and this is hypothesized to rely on a more sophisticated manner of thinking about and relating to other people – including understanding their mental states.

Recently, we adapted a task that requires the online use of theory of mind information when making decisions in a communication game, and which produces large numbers of errors even in adults.[11] In our computerized version of the task, participants view a set of shelves containing objects, which they are instructed to move by a 'Director', who can see some but not all of the objects (Figure 2).[12] Correct interpretation of critical instructions requires participants to use the director's perspective and only move objects that the director can see (the director condition). We tested participants aged between 7 and 27 years and found that, while performance in the director and a control condition followed the same trajectory (improved accuracy) from mid-childhood until mid-adolescence, the mid-adolescent group made more errors than the adults in the director condition only. These results suggest that the ability to take another person's perspective to direct appropriate behaviour is still undergoing development at this relatively late stage.

Implications for society

There are many questions that remain to be investigated in this new and rapidly expanding field. The study of neural development during adolescence is likely to have important implications for society in relation to education and the legal treatment of teenagers, as well as a variety of mental illnesses that often have their onset in adolescence.[13]



Research into the cognitive implications of continued brain maturation beyond childhood may be relevant to the social development and educational attainment of adolescents. Further studies are necessary to reach a consensus about how brain development impacts on social, emotional, linguistic, mathematical and creative development. In other words, which skills undergo perturbation, which undergo sensitive periods for enhancement and how does the quality of the environment interact with brain changes in the development of cognition? Longitudinal studies of the effect of early deprivation on the cognitive development of Romanian adoptees in the UK have begun to investigate this question.[14] Whether greater emphasis on social and emotional cognitive development would be beneficial during adolescence is unknown but research will provide insights into potential intervention schemes in secondary schools, for example, for remediation programs for antisocial behaviour.

Understanding the brain mechanisms that underlie learning and memory, and the effects of genetics, the environment, emotion and age on learning could transform educational strategies and enable us to design programs that optimize learning for people of all ages and of all needs. Neuroscience can now offer some understanding of how the brain learns new information and processes this information throughout life.[15] Understanding the brain basis of social functioning and social development is crucial to the fostering of social competence inside and outside the classroom. Social functioning plays a role in shaping learning and academic performance (and vice

Figure 2

a, b. Images used to explain the Director condition: participants were shown an example of their view (a) and the corresponding director's view (b) for a typical stimulus with four objects in occluded slots that the director cannot see (e.g. the apple); c, d. Example of an experimental (c) and a control trial (d) in the Director condition. The participant hears the verbal instruction: 'Move the small ball left' from the director. In the experimental trial (c), if the participant ignored the director's perspective, she would choose to move the distractor ball (golf ball), which is the smallest ball in the shelves but which cannot be seen by the director, instead of the larger ball (tennis ball) shared by both the participant's and the instructor's perspective (target). In the control trial (d), an irrelevant object (plane) replaces the distractor item

versa), and understanding the neural basis of social behaviour can contribute to understanding the origins and process of schooling success and failure. The finding that changes in brain structure continue into adolescence (and beyond) has challenged accepted views, and has given rise to a recent spate of investigations into the way cognition (including social cognition) might change as a consequence. Research suggests that adolescence is a key time for the development of regions of the brain involved in social cognition and self-awareness. This is likely to be due to the interplay between a number of factors, including changes in the social environment and in puberty hormones, as well as structural and functional brain development and improvements in social cognition.

If early childhood is seen as a major opportunity – or a 'sensitive period' - for teaching, so too should the teenage years. During both periods, particularly dramatic brain reorganization is taking place. The idea that teenagers should still go to school and be educated is relatively new. And yet the research on brain development suggests that education during the teenage years is vital. The brain is still developing during this period, is adaptable, and needs to be moulded and shaped. Perhaps the aims of education for adolescents might change to include abilities that are controlled by the parts of the brain that undergo most change during adolescence. These abilities include internal control, multi-tasking and planning – but also self-awareness and social

Downloaded from jrs.sagepub.com at GEORGETOWN UNIV MED CTR on May 25, 2015

cognitive skills such as perspective taking and the understanding of other people's minds.

Conclusion

The study of brain development beyond childhood is a new but rapidly evolving field with applications for education and social policy. The finding that changes in brain structure and function continue into adolescence has challenged accepted views. In this paper, I have focused on research in developmental cognitive neuroscience, but a richer account of changes in adolescent learning, strategic and social behaviour requires a multidisciplinary approach that recognizes the complex interactions between genetics, brain structure, physiology and chemistry, and the environment.

REVIEW

Stress, Depression, and Neuroplasticity: A Convergence of Mechanisms

Christopher Pittenger[1] and Ronald S Duman*,[1]

[1]*Department of Psychiatry, Connecticut Mental Health Center, Yale University School of Medicine, New Haven, CT, USA*

Increasing evidence demonstrates that neuroplasticity, a fundamental mechanism of neuronal adaptation, is disrupted in mood disorders and in animal models of stress. Here we provide an overview of the evidence that chronic stress, which can precipitate or exacerbate depression, disrupts neuroplasticity, while antidepressant treatment produces opposing effects and can enhance neuroplasticity. We discuss neuroplasticity at different levels: structural plasticity (such as plastic changes in spine and dendrite morphology as well as adult neurogenesis), functional synaptic plasticity, and the molecular and cellular mechanisms accompanying such changes. Together, these studies elucidate mechanisms that may contribute to the pathophysiology of depression. Greater appreciation of the convergence of mechanisms between stress, depression, and neuroplasticity is likely to lead to the identification of novel targets for more efficacious treatments.
Neuropsychopharmacology Reviews (2008) **33,** 88–109; doi:10.1038/sj.npp.1301574; published online 12 September 2007

Keywords: synapse; neurogenesis; antidepressant; signal transduction; gene expression

INTRODUCTION

Over the past 50 years, different categories of effective antidepressant medications have been fortuitously discovered. All available antidepressants act on the brain's modulatory monoamine systems, an observation that formed the core of the monoamine hypothesis of the pathophysiology of depression (Heninger *et al*, 1996). More recently, molecular events downstream of antidepressants' direct actions on the monoamines have been elucidated, generating new theories about the pathophysiology of depression and the action of antidepressant medications (Duman *et al*, 1997), and new families of potential targets for novel antidepressant therapies (Manji *et al*, 2003).

A startling observation, as these downstream molecular events have been elucidated, is the striking degree of overlap between the molecular and cellular changes induced by antidepressant treatment and the molecular mechanisms of neuroplasticity, especially synaptic plasticity (see review by Citri and Malenka in this volume). Perhaps the most well-characterized instance of this fact is the transcription factor CREB, which has a well-established role in learning-related synaptic plasticity in many organisms and brain regions (eg Bartsch *et al*, 1998; Pittenger *et al*, 2002; reviewed in Carlezon *et al*, 2005) and is involved in the hippocampus in antidepressant response (Thome *et al*, 2000; Chen *et al*, 2001a). Similar parallels have now been found in a multitude of other molecular events, synaptic alterations, and morphological changes, as we further review below. While the precise nature of the relationship between the pathophysiology of major depression and possible dysfunction of neuroplasticity remains poorly understood, it is likely that an intimate relationship exists.

In parallel, the interactions between chronic stress or a dysregulated stress response and the molecular, cellular, and behavioral changes that attend the development of a depression-like state have become increasingly clear. The relationship between psychosocial stressors and the development of depression in susceptible individuals has long been apparent (Kendler *et al*, 1999; Caspi *et al*, 2003). In experimental animals, stress can lead to atrophy of the hippocampus similar to that seen in depression (Sapolsky, 2000); chronic stress paradigms in animals recapitulate many of the core behavioral characteristics of depression and are responsive to antidepressant treatment (reviewed in Willner, 2005). The details remain to be elucidated, but any comprehensive picture of the pathophysiology of depression must include the role of stress in the etiology of the disorder.

Completing the circle, there is increasing appreciation of the effects of stress on the mechanisms of neuroplasticity (Shors *et al*, 1989; reviewed in McEwen, 1999). Clearly, then, there is an intimate relationship between the effects of stress, the mechanisms of neuroplasticity, and the pathophysiology of depression and mechanisms of antidepressant action.

Received 11 July 2007; revised 3 August 2007; accepted 4 August 2007

We explore this relationship in this review, outlining the major molecular and cellular pathways related to neuroplasticity that are altered by stress and appear to contribute to behaviors related to depression. We then discuss the mechanisms of antidepressant response, their overlap with mechanisms of neuroplasticity, and how they oppose the effects of chronic stress in various behavioral models. Together, these studies support a model of disruption of neuroplasticity by stress that contributes importantly to the pathophysiology of depression, and that is blocked or reversed by antidepressant treatment.

IMPAIRMENTS OF LEARNING AND MEMORY IN MAJOR DEPRESSION

Cognitive impairment is a core endophenotype of major depression (Hasler *et al*, 2004). One of the formal diagnostic criteria for the syndrome is a 'diminished ability to think or concentrate' (American Psychiatric Association, 2000), and patients often complain of difficulty with cognitive function during everyday tasks.

Cognitive difficulties in major depression fall into at least two domains, which are likely to correspond to different underlying disruptions of brain function. First, as indicated by the diagnostic criteria, is impairment of concentration and attention. Because the dorsolateral prefrontal cortex (DLPFC) is well established to play a critical role in these capacities, both in healthy humans and in experimental animals (Goldman-Rakic, 1996), this symptom is likely to relate to the well-documented abnormalities of DLPFC function in subjects with major depression (Baxter *et al*, 1989; Harvey *et al*, 2005) and to the finding of neuropathological change in this region in post-mortem tissue (Rajkowska *et al*, 1999, 2007).

Patients with major depression—both first episode and recurrent—also exhibit prominent deficits in explicit memory (Zakzanis *et al*, 1998), a cognitive capacity well established to depend on the function of the hippocampus and the medial temporal lobe (Squire *et al*, 2004). Hippocampal atrophy has been repeatedly documented in major depression: while the total number of neurons and glia has not been found to be altered, neurons are reduced in size and the volume of the neuropil is reduced (Stockmeier *et al*, 2004). Correspondingly, structural imaging has demonstrated decreased hippocampal size in patients with major depression, especially those who have suffered multiple episodes (MacQueen *et al*, 2003). It remains to be established whether reduced hippocampal size is the cumulative result of multiple major depressive episodes or whether it precedes the multiple episodes and represents a trait marker of vulnerability for recurrent disease; the two possibilities need not be mutually exclusive.

Disruption of hippocampal function, including the capacity for neuroplasticity, could contribute to several aspects of major depression. In addition to its clear role in declarative memory, the hippocampus is a key regulator of prefrontal cortical function; hippocampus and DLPFC function cooperatively to regulate explicit memory. Disruption of hippocampal function in major depression could therefore contribute to the observed deficits in concentration, described above. Hippocampal afferents are also critical regulators of both the nucleus accumbens and the ventral tegmental area (VTA). It has been hypothesized that an indirect excitatory projection from hippocampus to VTA is critical for coordinating the firing of VTA cells in response to novelty (Lisman and Grace, 2005); impairment of this hippocampal function could thus lead to reduced dopaminergic tone and contribute to anhedonia (Warner-Schmidt and Duman, 2006). Finally, the hippocampus provides an important source of negative modulation of the hypothalamus–pituitary–adrenal stress hormone axis through its projections to the hypothalamus; hippocampal dysfunction therefore may contribute to the dysregulation of the stress response that is seen in major depression.

STRESS EFFECTS ON NEUROPLASTICITY: A PATHOPHYSIOLOGICAL CONTRIBUTOR TO MAJOR DEPRESSION?

Chronic stress has many effects on the central nervous system, including effects on neuroplasticity in brain structures that are functionally abnormal in major depression. Given the clear clinical relationship between stress and major depression, these effects represent candidate pathophysiological links between stress, the mechanisms of neuroplasticity, and the development of major depressive disorder (MDD).

Hippocampus: Effects of Prolonged Stress on Hippocampus-Dependent Memory, Plasticity, Cell Survival, and Neurogenesis

Transient mild stress can enhance learning and memory (Luine *et al*, 1996). However, chronic or severe stress is decidedly disruptive of hippocampus-dependent memory in experimental animals (Conrad *et al*, 1996; de Quervain *et al*, 1998; Diamond *et al*, 1999; reviewed in Sapolsky, 2003). Extended or high-dose treatment with glucocorticoids has a similar effect (Bodnoff *et al*, 1995; de Quervain *et al*, 1998). Specific impairments of hippocampus-dependent explicit memory are also seen after treatment of human subjects with glucocorticoids (Newcomer *et al*, 1999; de Quervain *et al*, 2000) and after stress (reviewed in Shors, 2005).

Hippocampal synaptic plasticity, as modeled by long-term potentiation (LTP), is widely believed to represent an important component mechanism of hippocampus-dependent memory formation (Malenka and Bear, 2004; see Figure 1). It is therefore striking that a sufficiently severe stress can impair LTP in the rodent hippocampus (Foy *et al*, 1987; Shors *et al*, 1989; reviewed in Kim and Diamond, 2002). Conversely, similar stress paradigms in rodents enhance long-term depression (LTD) in the hippocampus (Xu *et al*, 1997); the two effects are likely to have overlapping mechanisms, as both are prevented by *N*-methy-D-aspartate (NMDA) blockade during the behavioral stress (Kim *et al*, 1996). The effect of serum glucocorticoids mirrors that of stress: low levels of glucocorticoids amplify LTP (perhaps through preferential activation of hippocampal mineralocorticoid receptors), while higher levels attenuate it (perhaps because they saturate the mineralocorticoid receptors and lead to robust activation of glucocorticoid receptors; reviewed in De Kloet, 2004).

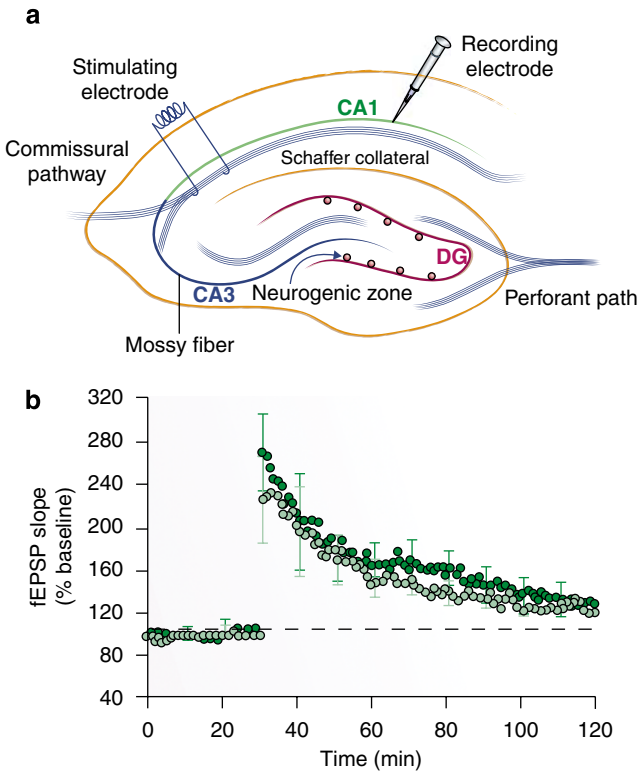

Figure 1 Hippocampal anatomy and sites of well-characterized forms of neuroplasticity. Neuroplasticity has been particularly intensively studied in the hippocampus. (a) Anatomy of the rodent hippocampus in coronal section is shown. Major synaptic projections include the perforant path from entorhinal cortex to dentate gyrus, the mossy fiber pathway from dentate gyrus to area CA3, and the Schaffer collateral pathway from area CA3 to area CA1. Other pathways exist but have been less intensively studied and are left out for clarity. Neurogenesis occurs in the subgranular cell zone of the dentate gyrus. (b) Synaptic plasticity has been characterized in all major synaptic pathways, but has been particularly intensively studied in the Schaffer collateral pathway; typical placement of stimulating and recording electrodes in an *in vitro* LTP experiment is shown.

Sustained levels of stress or glucocorticoids also damage the hippocampus at the level of morphological neuroplasticity (reviewed in Sapolsky, 2000) (Figure 2). Excess glucocorticoids (Woolley *et al*, 1990) or behavioral stress (Watanabe *et al*, 1992; Magarinos *et al*, 1996) lead to atrophy and retraction of the apical dendrites of hippocampal pyramidal cells; this effect leads to a reduction in the amount of neuropil without frank cell loss, reminiscent of what has been documented in the post-mortem hippocampus of patients with major depression (Stockmeier *et al*, 2004). Prolonged high-dose corticosterone—at higher levels than are typically achieved *in vivo*—can even result in death of hippocampal pyramidal cells (Sapolsky *et al*, 1985).

A final mechanism whereby prolonged stress can negatively impact hippocampal function and capacity for neuroplasticity has come to light more recently, with the broad acceptance of the presence of neurogenesis in the adult hippocampus (Figure 2). Many different forms of acute and chronic stress have been shown to reduce neurogenesis in the rodent hippocampus (reviewed in Duman, 2004; Dranovsky and Hen, 2006). Elevated levels of glucocorticoids likewise suppress hippocampal neurogenesis (Gould *et al*, 1992). As neurogenesis appears to be required for the behavioral response to antidepressants in rodents (Santarelli *et al*, 2003; see below) and impaired neurogenesis has been hypothesized to represent a core pathophysiological feature of major depression (Duman, 2004), this effect represents yet another way that the effects of stress on mechanisms of neuroplasticity may contribute to the development of depression.

Prefrontal Cortex: Effects of Prolonged Stress on Morphology and Function

While synaptic and morphological plasticity have been less intensively studied in the prefrontal cortex (PFC) than in the hippocampus, it is increasingly clear that stress has

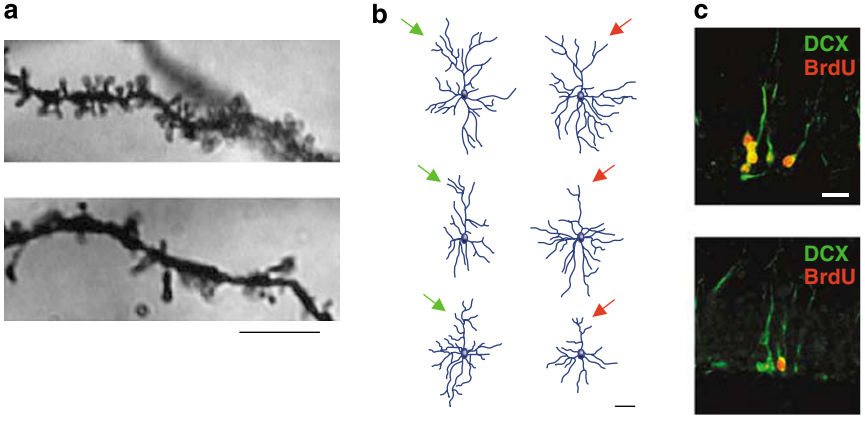

Figure 2 Stress alters neuroplasticity at multiple structural levels. (a) Chronic stress can reduce the number of dendritic spines. In this example, 8 weeks of postweaning social isolation produced a significant reduction in dendritic spines in mPFC in stress rat (lower panel) compared to controls (upper panel), as visualized by Golgi-Cox staining. From Silva-Gomez *et al*, 2003, with permission; scale bar = 5 μm. (b) Chronic stress can reduce the length and complexity of coritcal dendrites. In this example, repeated restraint stress (3 h a day for 3 weeks) produced shorter and less complex apical dendrites (indicated by arrows) in stressed rats (on the right) as compared to controls (on the left), as visualized in mPFC pyramidal neurons by computer-assisted resconstructions from Golgi-stained material. From Cook and Wellman, 2004, with permission; scale bar = 50 μm. (c) Chronic stress can impair neurogenesis. In this example, 3 weeks of daily unpredictable stressors reduced the generation of new neurons in the rat dentate gyrus (lower panel) compared to unstressed controls (upper panel). Neurogenesis is visualized by labeling with bromo-deoxyuridine (BrdU), which labels recently divided cells, and doublecortin (DCX), a marker of immature neurons. Ja-Wook Kim and RSD; scale bar = 20 μm.

similar effects on the mechanisms of neuroplasticity there. Chronic restraint stress induces significant regression of the apical dendrites of pyramidal cells in medial prefrontal cortex (mPFC) in rats, an effect similar to that described in area CA3 of the hippocampus (Cook and Wellman, 2004; Radley *et al*, 2004). The effect may be specific to mPFC, as orbital PFC is spared (Liston *et al*, 2006). Attentional set-shifting, a behavioral task that depends on intact mPFC function, is impaired in chronically stressed animals (Liston *et al*, 2006). A similar effect is seen following chronic administration of corticosterone (Wellman, 2001). Again, this morphological change appears to recapitulate some of the changes seen in post-mortem tissue from patients with MDD (Rajkowska *et al*, 1999).

One of the most consistent neuropathological findings in MDD is a reduction in the number of glia (Ongur *et al*, 1998; Rajkowska *et al*, 1999; Cotter *et al*, 2001, 2002; Uranova *et al*, 2004). In animals, chronic unpredictable stress results in a reduction in the proliferation of glia and endothelial cells in the mPFC (Banasr *et al*, 2007); exposure to glucocorticoids causes a similar effect (Alonso, 2000). Glia provide metabolic support for neurons; a reduction in the numbers of these cells could impact the function as well as morphology of mPFC pyramidal cells. Glia also play an important role in both the synthesis and inactivation of glutamate, which is central to many forms of neuroplasticity (a point to which we return below). Altered number or function of glia could thereby impact neuroplasticity. Stress-induced reductions in glial proliferation could contribute to the decrease in glial number observed in MDD and to a decrease in neural plasticity.

It is tempting to speculate that such stress-induced atrophy of prefrontal dendrites and a reduction in glial number contribute to the 'hypofrontality' observed in patients with major depression (see above). Some data support an effect of chronic stress on prefrontal physiology and information processing. For example, acute stress can perturb synaptic plasticity at the projection from amygdala to PFC (Maroun and Richter-Levin, 2003). At the reverse projection, from PFC to amygdala, stress shifts the balance from one that favors LTD to one that favors LTP (Maroun, 2006).

While the precise contribution of such perturbations to the network changes in brain function that characterize the depressed state is difficult to infer, these findings support the notion that sufficient levels of stress alter the mechanisms of neuroplasticity in a group of interconnected structures, which are functionally abnormal in major depression. Furthermore, even though only a few studies have examined synaptic plasticity in these structures after stress, the directions of the documented changes are concordant with the abnormalities seen in major depression. PFC is hypoactive in major depression; and potentiation of a major excitatory pathway leading to it is attenuated by stress. Conversely, the amygdala is hypertophic and hyperactive in major depression, and potentiation of a major input to it—from the ventro mPFC —is enhanced.

Amygdala: Stress-Induced Hypertrophy

Whereas the hippocampus and PFC are both reduced in size and activity in major depression, the amygdala's size and activity are increased (reviewed in Drevets, 2003). Several structural imaging studies have reported increased amygdala volume in patients with major depression (Bremner *et al*, 2000; Frodl *et al*, 2002; Lange and Irle, 2004). The amygdala has also been found to be hyperactive in major depression (Drevets *et al*, 1992); its activity correlates with the intensity of negative affect (Drevets *et al*, 1992; Abercrombie *et al*, 1998).

Chronic stress can enhance amygdala-dependent learning, in contrast to its effects on hippocampus-dependent declarative learning. In rats, chronic stress enhances amygdala-dependent fear learning (Conrad *et al*, 1999). It also enhances behavioral measures of anxiety in experimental animals (Conrad *et al*, 1999; Vyas *et al*, 2004).

Correspondingly, stress enhances synaptic plasticity and the function of amygdala neurons, an effect quite distinct from the atrophy it induces in the hippocampus and PFC. This could both result from and contribute to over-activation of neuronal circuits that control fear, anxiety, and emotion. In rats, stress that leads to atrophic changes in hippocampal pyramidal cells produces enhanced dendritic length and branching in amygdala principal cells and in the bed nucleus of the stria terminalis, an important amygdala projection target (Vyas *et al*, 2002, 2003). Prolonged stress increases dendritic spines and synaptic connectivity in the amygdala (Vyas *et al*, 2006). Interestingly, these changes do not reverse even several weeks after the cessation of the chronic stressor (Vyas *et al*, 2004). Indeed, the effects of stress on the amygdala maybe very long-lasting indeed: in rats, prenatal stress can lead to increased amygdala size in adulthood (Salm *et al*, 2004). If replicated and extended, such findings have clear implications for the pathophysiological relationship between early life stress and subsequent vulnerability to major depression.

The contrast between the effects of stress on the amygdala and those on the hippocampus and PFC is striking. Whereas acute and chronic stress impair hippocampal function, reduce the length and complexity of CA3 dendrites, and impair neurogenesis, very similar treatments lead to enhanced amygdala-dependent fear learning, increased length and complexity of amygdalar dendrites, and increased amygdala size. This contrast makes it clear that the well-documented effects of stress on hippocampal morphology and function are not manifestations of a universal effect of stress hormones or other aspects of stress on neuronal integrity. Rather, the effects of stress on brain morphology and function are region and circuit dependent. Both acute and chronic stress can have very different effects of different brain regions and functions, a fact with profound implications for our understanding of the pathophysiology of major depression.

Ventral Striatum: Stress-Associated Changes in Neuroplasticity and the Mechanisms of Reward

A final structure in which neuroplasticity may relate to effects of stress and the symptoms of depression is the ventral striatum, including the nucleus accumbens. The accumbens has a central role in the mechanisms of natural reward; as such, its dysregulation in depression is thought to relate to symptoms of anhedonia (Dunn *et al*, 2002; Nestler and Carlezon, 2006). A recent neuroimaging study

supports this view, finding attenuated accumbens activation in response to positive visual stimuli in depressed subjects (Epstein *et al*, 2006). The relevance of such dysfunction, both to pathophysiology and to future therapies, was dramatically demonstrated by the successful treatment of several cases of profoundly refractory depression by deep brain stimulation of the nucleus accumbens (Schlaepfer *et al*, 2007).

Stress can activate the dopaminergic projection to the accumbens from the VTA; this may contribute to a homeostatic response to stress or to adaptive stress-related learning. However, chronic stress can cause long-term adaptations in the VTA–accumbens pathway (Ortiz *et al*, 1996; Saal *et al*, 2003) that may contribute to its dysregulation in major depression (reviewed in Nestler and Carlezon, 2006). Though plasticity in this pathway under conditions of stress and depression remains sparsely studied, it is likely to represent an important component of any comprehensive view of the relationship between stress, depression, and neuroplasticity.

MOLECULAR AND CELLULAR MECHANISMS OF NEUROPLASTICITY

The mechanisms of synaptic and morphological plasticity have been extensively studied in the context of their contribution to learning and memory (Malenka and Bear, 2004; Citri and Malenka, this volume). It is here that some of the most striking parallels between the mechanisms of neuroplasticity and those underlying MDD emerge, especially in the overlap between the cellular mechanisms of synaptic plasticity and the molecular and cellular changes that attend antidepressant treatment. A dizzying array of molecular components has been implicated in synaptic plasticity in various systems (Sanes and Lichtman, 1999); it is not our intention to comprehensively review this vast literature. Rather, we emphasize some of the common themes in studies of synaptic and structural plasticity, and some of the specific molecular players most cogent to a subsequent discussion of the mechanisms of antidepressant response.

Inducers and Local Mechanisms of Synaptic Plasticity

Mechanistically distinct forms of experimentally induced synaptic plasticity have been described in a number of different systems (Malenka and Bear, 2004). A common theme is that many forms of synaptic potentiation are triggered by increases in synaptic calcium influx and in the local concentration of the second messenger molecule cyclic AMP (cAMP). These pathways are particularly well suited to the requirements of a plasticity-inducing mechanism. Local calcium influx, for example, commonly derives from the NMDA receptor, which is a highly evolved coincidence detector—it is activated only when presynaptic and postsynaptic cells are depolarized simultaneously. Such coincidence detection is precisely what is required for many forms of homosynaptic plasticity (Hebb, 1949). cAMP is regulated by many modulatory neurotransmitters, including serotonin, dopamine, and norepinephrine, as well as by calcium; it is therefore optimally suited for the integration of synaptic events with the modulatory influences of global variables such as arousal and attention.

Local elevations in calcium and cAMP induce events required for short-term synaptic plasticity. For example, the calcium-calmodulin-dependent kinase II (CaMKII), which is activated by local increases in calcium, is critical for early LTP. CaMKII has unique properties that make it well suited to a role in the induction of synaptic plasticity. Upon induction by a sufficient rise in the local concentration of calcium, it can phosphorylate itself. Autophosphorylated CaMKII is persistently active, even after calcium levels fall. This mechanism allows an inducing pulse of calcium to lead to more persistent activation of CaMKII, and thereby to activation of downstream processes that result in synaptic change (Lisman and Goldring, 1988).

Several other calcium-calmodulin kinases exist in neurons. CaMKIV, in particular, is prominent in the neuronal nucleus, where it is an important activator of regulated transcription factor such as CREB (Bito *et al*, 1996). Inhibition of CaMKIV impairs both long-lasting forms of LTP and long-lasting hippocampus-dependent learning (Kang *et al*, 2001). Calcium calmodulin-dependent kinases can thus contribute to both short-term and long-lasting neuroplasticity.

Both CaMKII and other kinases can phosphorylate the GluR1 subunit of the AMPA glutamate receptor and associated proteins. This phosphorylation both increases the number of AMPA receptors in the postsynaptic membrane (by triggering insertion of new AMPA receptors) and enhances the function of those receptors already inserted. Both mechanisms contribute to an enhancement of synaptic strength.

At the structural level, insertion of AMPA receptors can result in the activation of 'silent synapses' (Malenka and Nicoll, 1997). A silent synapse is a synaptic connection at which the postsynaptic membrane contains only NMDA receptors (Figure 3). Because of the NMDA receptor's coincidence detection properties, such a synapse is not activated by simple depolarization of the presynaptic cell. Upon the induction of LTP, AMPA receptors are inserted into the postsynaptic membrane at such a synapse, rendering it active upon subsequent single presynaptic impulses (hence no longer 'silent'). This unsilencing of silent synapses contributes to synaptic strengthening and appears to be a major mechanism of LTP.

Transduction to the Nucleus

While short-term changes in synaptic strength can be mediated by local events at the synapse, such as AMPA receptor phosphorylation and insertion into the postsynaptic membrane, longer-term changes require a broader coordination of cellular mechanisms—in particular, induction of genes and production of new protein (Nguyen *et al*, 1994). Upon sufficient local elevation of calcium and cAMP, therefore, signal transduction cascades are activated that transmit the inducing signal to the nucleus (Kandel, 2001). (Specific signaling molecules, such as kinases and phosphatases, can participate both in local, early events and in signaling to the nucleus and the transition to more

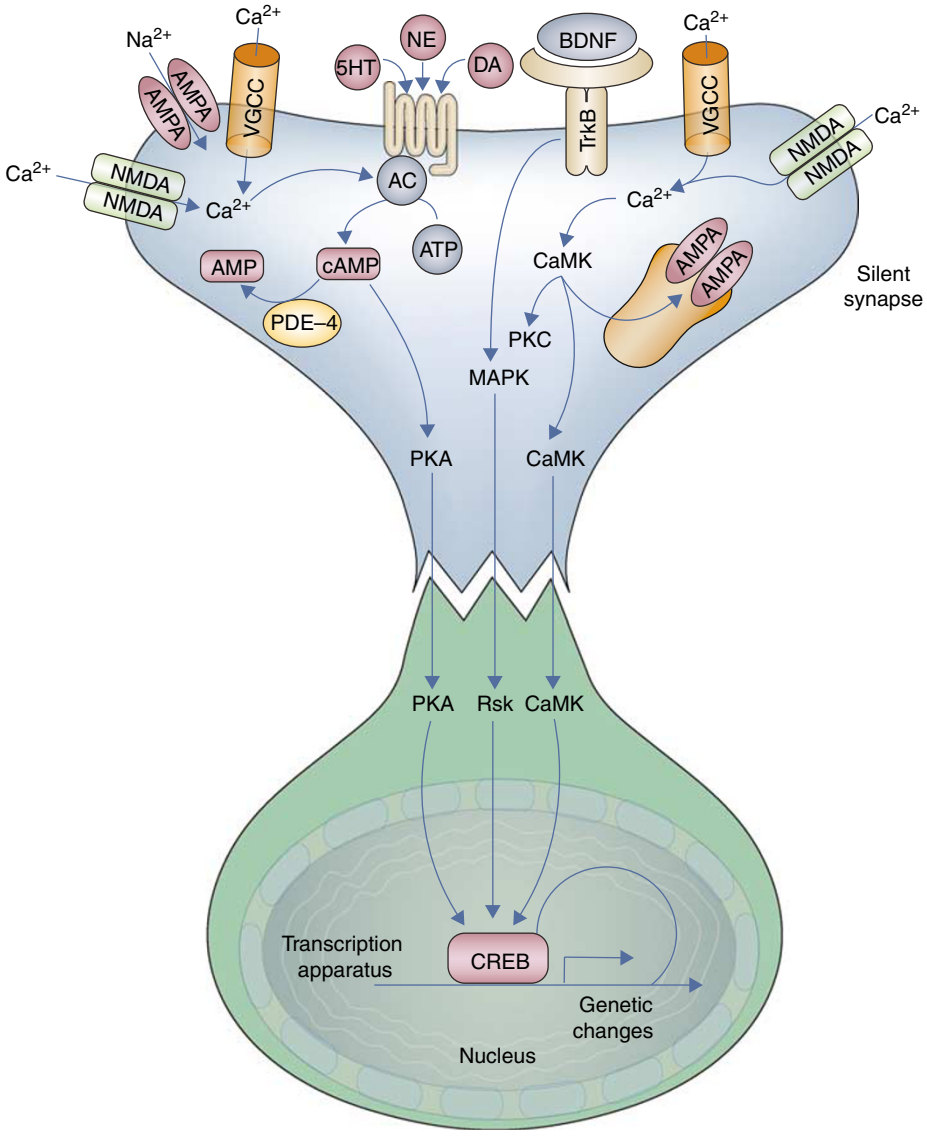

Figure 3 Major molecular pathways involved in neuroplasticity and affected by stress, depression, and antidepressant treatment. Some major molecular pathways involved in both short- and long-term neuroplastic changes are shown. Certain intermediates and other details are left out for clarity. Many of these pathways are influenced in opposite ways by stress and depression. For example, both chronic stress in animals and depression in humans have been associated with reductions in the transcription factor CREB, and antidepressants enhance CREB activity in the hippocampus. See text for further details and references. Abbreviations: NMDA, *N*-methyl-D-aspartate glutamate receptor; AMPA, amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid glutamate receptor; VGCC, voltage-gated calcium channel; 5-HT, 5-hydroxytryptamine (serotonin); NE, norepinephrine; DA, dopamine; BDNF, brain-derived neurotrophic factor; Trk-B, BDNF receptor; AC, adenylyl cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; AMP, adenosine monophosphate; PDE, phosphodiesterase; CaMK, calcium-calmodulin-dependent kinase; PKC, protein kinase C; MAPK, mitogen-activated protein kinase; PKA, protein kinase A; Rsk, ribosomal S6 protein kinase; CREB, cAMP response element-binding protein.

persistent forms of plasticity, as in the case of CaM kinases discussed above).

One signal transduction cascade that has been particularly clearly tied to the mechanisms of late-phase LTP (L-LTP) is the cAMP-dependent protein kinase, PKA (Abel *et al*, 1997). PKA consists of a regulatory and a catalytic subunit; at rest, the regulatory subunit binds to the catalytic subunit, inactivating it. Upon sufficient accumulation of cAMP, the two subunits dissociate, freeing the catalytic subunit to phosphorylate a variety of substrates. Since cAMP is increased by β-adrenergic, 5-HT4, 6, 7, and dopamine D1 receptors, activation of PKA represents a mechanism by which modulatory neurotransmitters can influence the mechanisms of long-lasting synaptic plasticity.

Another signal transduction pathway that has been repeatedly implicated in signaling to the nucleus and the induction of L-LTP is the mitogen-activated protein kinase (MAPK) pathway. This cascade of kinases is critical for the induction of long-lasting synaptic plasticity in the hippocampus, amygdala, and cortex (Atkins *et al*, 1998; Huang *et al*, 2000; Di Cristo *et al*, 2001; reviewed in Giovannini, 2006). MAPK translocates to the nucleus upon induction of L-LTP, where it can activate nuclear substrates (Patterson *et al*, 2001).

The induction of new genes in support of L-LTP requires that such signaling systems activate regulated transcription factors in the nucleus. There are likely to be many such regulated transcription factors involved in coordinating the genes that contribute to long-lasting synaptic change. Particularly, strong evidence implicates the transcription factor CREB in the regulation of numerous forms of synaptic change: it is activated upon synaptic stimulation and after learning in the hippocampus, amygdala, and cortex; and CREB inhibition in these and other brain regions disrupts LTP and corresponding forms of long-lasting memory (Glazewski *et al*, 1999; Pittenger *et al*, 2002, 2006; Kida *et al*, 2002; reviewed in Carlezon *et al*, 2005). CREB can be activated by a variety of kinases, including PKA and (indirectly) the MAPK cascade.

Effector Genes—Neurotrophins and Structural Change

CREB, and other inducible transcription factors, induce effector genes that contribute to the stabilization of synaptic plasticity (Kandel, 2001). Prominent among these is brain-derived neurotrophic factor (BDNF), which is induced by LTP and has a critical role in stabilizing synaptic change (Patterson *et al*, 1992). Once again, this has been demonstrated in hippocampus (Patterson *et al*, 1996), amygdala (Rattiner *et al*, 2005), and cortex (Bartoletti *et al*, 2002). Knockout of BDNF is lethal because of its multiple developmental roles, complicating analysis of its role in learning and memory; but recent studies that have disrupted BDNF only in the adult animal indicate a critical role in information processing and storage (Monteggia *et al*, 2004; Heldt *et al*, 2007; reviewed in Pang and Lu, 2004).

BDNF acts by multiple mechanisms and influences both early and late phases of synaptic plasticity, in both the presynaptic and the postsynaptic cells. It acts, at least in part, via the MAPK signaling cascade, suggesting that this pathway plays multiple roles in the regulation of plasticity. Other growth factors have also been demonstrated to influence LTP, including vascular endothelial growth factor (VEGF; Cao *et al*, 2004). Like BDNF, VEGF activates the MAPK cascade and has been implicated in the actions of stress and antidepressant treatments, as will be further discussed below.

It has long been hypothesized that long-lasting synaptic change is likely to correspond to morphological change at potentiated (or depressed) synapses. In recent years, growth of new dendritic spines and enlargement of existing spines have been demonstrated after LTP-inducing synaptic stimulation (Engert and Bonhoeffer, 1999; Matsuzaki *et al*, 2004). As a neurotrophic factor, with a critical role in stabilizing neurons during development, BDNF is well equipped to participate in such changes. The same is true for other LTP-induced secreted factors such as the tissue plasminogen activator (Pang and Lu, 2004) and cell adhesion molecules such as NCAM (Bukalo *et al*, 2004).

Positive and Negative Regulators of Neuroplasticity

As is expected of any important physiological process, synaptic potentiation and other forms of neuroplasticity are controlled by both positive and negative regulatory mechanisms (Abel *et al*, 1998). LTD may under some circumstances provide a homeostatic counterbalance to excessive synaptic potentiation (Tononi and Cirelli, 2006). Inhibitors of the signal transduction cascades that contribute to synaptic potentiation also provide a counterbalancing influence. Examples include phosphatases such as calcineurin (Malleret *et al*, 2001), which can antagonize signaling through the MAPK cascade, and phosphodiesterases, which break down cAMP and thus attenuate PKA-mediated signaling and other cAMP-dependent processes (Barad *et al*, 1998).

Recent studies have revealed that the NMDA receptor, which is the canonical initiator and positive regulator of LTP, can have contrary effects depending on its subcellular localization. Specifically, while synaptically localized NMDA receptors can trigger LTP, positively regulate MAPK, CREB and BDNF, and contribute to long-lasting plasticity and cell survival, activation of extrasynaptic NMDA receptors has the opposite effects, inhibiting CREB activation and the production of BDNF (Hardingham *et al*, 2002). It has been proposed that robust activation of extrasynaptic NMDA receptors may be an important contributor to excitotoxic cell death (Hardingham and Bading, 2003). Imbalance between stimulation of synaptic and extrasynaptic receptors may contribute to pathological states, including depression (as will be further explored below; reviewed in Pittenger *et al*, 2007).

Neurogenesis

Contrary to long-standing dogma, clear evidence now demonstrates that new neurons are generated in the adult mammalian brain; neurogenesis is prominent in the dentate gyrus region of the hippocampal formation (Altman and Das, 1965; Kaplan and Hinds, 1977; Kempermann *et al*, 1997; reviewed in Ming and Song, 2005).

The specific functional role and relevance of these new neurons is less firmly established; but a link between neurogenesis and the learning-related functions of the hippocampus is an intriguing possibility. Several lines of evidence support such a functional link (Leuner *et al*, 2006). Some computational theories of hippocampal function predict a role for new neurons in hippocampus-dependent learning (Chambers *et al*, 2004). Performance in a hippocampus-dependent spatial learning task correlates with the number of new neurons in aged rats (Drapeau *et al*, 2003), suggesting a functional contribution to learning. Electrical activity has been shown to be coupled with neurogenesis in the hippocampus, suggesting a mechanism whereby recruitment of the hippocampus during learning may lead to the production and incorporation of new neurons into the circuit (Deisseroth *et al*, 2004).

Behavioral studies in animals in which neurogenesis has been experimentally perturbed lend support to the idea that the new cells play a critical causal role in some forms of hippocampus-dependent learning. Administration of a chemotherapeutic agent that kills dividing cells impairs step-down avoidance, which depends on the function of the hippocampus (along with other structures; Shors *et al*, 2001). Saxe *et al* (2006) found that ablation of new neurons impaired dentate gyrus LTP (as measured *in vitro*) and

hippocampus-dependent contextual fear conditioning, but did not affect cued fear conditioning (which does not require the hippocampus). Data on the role of the new neurons in spatial learning are conflicting: Saxe *et al* (2006) found ablation of the new neurons to spare spatial learning in the Morris water maze, while others have found interference with neurogenesis to compromise spatial learning (Snyder *et al*, 2005). Further studies will be needed to clarify the role that new hippocampal neurons play in learning and memory.

Mechanisms initially implicated in the induction of LTP are likely also to be important in the regulation of neurogenesis. For example, activation of CREB promotes neurogenesis (Nakagawa *et al*, 2002a), and blockade of CREB function decreases neurogenesis (Nakagawa *et al*, 2002a, b). Likewise, growth factors regulate both the proliferation (VEGF; Cao *et al*, 2004) and survival (BDNF; Sairanen *et al*, 2005) of new hippocampal neurons.

This outline of molecular pathways contributing to neuroplasticity is necessarily selective and incomplete. More thorough treatments are given elsewhere (Malenka and Bear, 2004; Citri and Malenka, this volume), although this literature is so vast that it has become virtually impossible to review comprehensively. It does, however, lay the groundwork for an examination of how behavioral stress and pharmacological treatment with glucocorticoids alter signaling pathways associated with neuroplasticity.

IMPACT OF STRESS ON THE MOLECULAR PATHWAYS OF NEUROPLASTICITY

We have reviewed above some of the evidence that stress can lead to alterations in morphological plasticity: regression of dendrites, reduction in spine density, and a shrinkage of the neuropil in hippocampus and PFC. We now turn to effects of stress on some of the molecular mechanisms underlying neuroplasticity.

As noted above, acute and chronic stress can have quite different effects on learning: while acute stress can potentiate learning (and LTP; Shors, 2001), chronic stress leads to deficits in hippocampus-dependent memory reminiscent of those seen in major depression. It is therefore to be expected that the downstream molecular changes resulting from stress or manipulations of stress hormones may depend sensitively on the intensity and duration of the stressor glucocorticoid excess. This issue has not yet been explored in sufficient experimental detail for firm conclusions to be drawn. In the brief review presented here, we merely point out evidence that stress and glucocorticoids, either acute or chronic, can influence mechanisms implicated in neuroplasticity, without attempting to draw firm conclusions about the specific functional consequences of specific alterations in plasticity mechanisms or about mechanistic distinctions that may exist between the effects of acute and chronic stress on these systems.

Contributions of Glutamate to Neuronal Atrophy after Stress

As reviewed above, chronic stress or elevations in glucocorticoids can lead to neuronal atrophy, especially to dendritic retraction in cells of the CA3 cell field and the mPFC. Convergent evidence suggests that glutamatergic excess is likely to contribute to this cell damage and even, in extreme cases, to cell death (Sapolsky, 2000, 2003). Acute stressors rapidly increase extracellular glutamate in the PFC (Bagley and Moghaddam, 1997). Glucocorticoid excess increases glutamate release in the CA1 region of the hippocampus (Venero and Borrell, 1999), and chronic behavioral stress increases extracellular levels of glutamate in the CA3 region (Lowy *et al*, 1993). Glutamate antagonists can attenuate or block some of the effects of chronic glucocorticoid excess on dendritic morphology in the hippocampus (Magariños and McEwen, 1995). Exposure to glucocorticoids increases expression of the primary glial glutamate transporter, GLT-1 (Zschocke *et al*, 2005; Autry *et al*, 2006); this may serve to increase reuptake of elevated extracellular glutamate in conditions of chronic stress.

The finding of elevated extracellular glutamate in conditions of chronic stress is, at first blush, at odds with the suggestion that chronic stress attenuates mechanisms of neuroplasticity. This apparent contradiction is perhaps clarified by the recent distinction between the function of synaptic and extrasynaptic NMDA receptors (Hardingham *et al*, 2002; Hardingham and Bading, 2003). Stress-induced increases in extrasynaptic glutamate may perturb the balance between synaptic and extrasynaptic NMDA tone and have a net inhibitory effect on the mechanisms of synaptic plasticity and neuronal growth and survival (reviewed in Pittenger *et al*, 2007).

The effects of chronic stress on glutamatergic neurotransmission can be seen in alterations in the expression of glutamate receptor genes. For example, glucocorticoids can enhance AMPA-mediated excitatory synaptic transmission (Karst and Joëls, 2005). This contrasts with the finding that maternal separation stress has been shown to lead to lasting reduction in the expression of the NMDA receptor subunit NR2B and of the AMPA receptor subunits GluR1 and GluR2 (Pickering *et al*, 2006); differences in the level and chronicity of stress or glucocorticoid exposure may explain these contrasting results, which merit further study.

Stress-Induced Alterations Plasticity-Associated Signaling Pathways

Stress can alter neuronal signaling in multiple ways. Scattered observations in the literature suggest that chronic stress can alter signaling pathways implicated in synaptic plasticity. For example, several forms of chronic stress have been observed to increase the phosphorylation of MAPK (Pardon *et al*, 2005; Lee *et al*, 2006). Acute glucocorticoid treatment likewise induces the phosphorylation of MAPK (Revest *et al*, 2005), and acute swim stress leads to the phosphorylation of both MAPK and CaMKII (Ahmed *et al*, 2006). This activation of MAPK appears to be critical for the effects of behavioral stress on hippocampal LTP (Yang *et al*, 2004).

Both acute and chronic stressors can also lead to increased phosphorylation of CREB in the hippocampus (Pardon *et al*, 2005; Ahmed *et al*, 2006), consistent with an alteration in signaling pathways linking synaptic activity to nuclear effects. In contrast, chronic glucocorticoid treatment impairs CREB activity in cultured neurons (Focking

et al, 2003); certain chronic mild stress paradigms have been reported to produce a similar effect (Grønli *et al*, 2006). Again, these contrasting results may relate either to differences in experimental paradigm (Nair *et al*, 2007) or to a central role for the intensity or duration of stressors on the downstream molecular perturbations that result.

Stress Regulation of Growth Factors

As noted above, signaling pathways implicated in neuroplasticity target, among other downstream targets, genes for growth factors such as BDNF. Both acute and chronic stress lead to reductions in hippocampal BDNF mRNA levels, suggesting an impairment of some of the mechanisms of neuroplasticity (Nibuya *et al*, 1995, 1999; Smith *et al*, 1995; Russo-Neustadt *et al*, 2001; Rasmusson *et al*, 2002; Franklin and Perrot-Sinal, 2006). Glucocorticoids likewise suppress BDNF expression (Smith *et al*, 1995; reviewed in Schaaf *et al*, 2000).

Other growth factors are likewise regulated by stress. For example, nerve growth factor, the paradigmatic developmental neurotrophin, has been reported to be upregulated by chronic stress (Alfonso *et al*, 2006). VEGF, a trophic factor induced by electroconvulsive seizure (Newton *et al*, 2003), is suppressed by chronic stress (Heine *et al*, 2005). Similarly, VEGF's angiogenic actions are impaired by glucocorticoid treatment (Kasselman *et al*, 2007). The involvement of trophic factors beyond BDNF suggests that a multifaceted machinery of neuronal support may be impaired by stress and, possibly, enhanced by antidepressant therapies (Newton and Duman, 2004).

Other Downstream Target Genes

Recently, gene profiling of animals exposed to stress has identified other genes that are differentially regulated by stress or glucocorticoids (Alfonso *et al*, 2004); many genes so identified have roles in neuroplasticity. For example, one study found decreases in the cell adhesion molecule NCAM (whose upregulation is critical for long-lasting LTP; Muller *et al*, 1996), the signaling molecule PKC-α, and the synaptic marker synapsin I in various chronic stress models (Alfonso *et al*, 2006). Further characterization of neuroplasticity-related genes dysregulated by different stressors will provide opportunities to identify which particular neuroplasticity-related mechanisms are most closely associated with the effects of acute and chronic stress in the brain.

ANTIDEPRESSANTS INDUCE NEUROPLASTICITY

If the effects of stress on the mechanisms of neuroplasticity contribute to the pathophysiology of depression, then antidepressant treatments might be expected to affect the same mechanisms. Substantial evidence suggests that this is in fact the case. In the simplest scenario, where chronic stress impairs the mechanisms of neuroplasticity, antidepressants would be predicted to have the opposite effect and enhance them. There are multiple situations in which this is in fact the case. Other instances are likely to be more complicated, as stress and antidepressant treatment impact the complicated and interacting mechanisms of neuroplasticity in contrasting but not directly opposite ways. A deepened appreciation of these interactions will inform our evolving understanding of the pathophysiology of depression and the mechanisms of antidepressant action, and is likely to guide the search for novel antidepressant strategies in the future.

Enhanced Neuroplasticity and Cognitive Function with Treatment in Depressed Patients

If depression entails a deficit in neuroplasticity, then antidepressant treatments may enhance neuroplasticity and even reverse deficits produced during the symptomatic period. Few studies to date have examined the effect of antidepressant therapies on cognition in normal human subjects, in part simply because of the ethical difficulties that would attend administration of chronic antidepressant therapy to patients who are not ill. One recent double-blind study suggested improvement in memory and a variety of other cognitive domains with chronic fluoxetine treatment in elderly patients with mild cognitive impairment (Mowla *et al*, 2007). Given the mounting evidence that antidepressant treatment can promote neuroplasticity, further studies of this sort, using antidepressants with a primary goal of enhancing impaired cognitive function, may be warranted.

A small literature does address the improvement of cognitive deficits, and even of structural damage, in patients treated with a variety of antidepressant therapies. Electroconvulsive therapy (ECT) is perhaps the most efficacious antidepressant therapy (and, incidentally, the one with the most profound effects on the mechanisms of neuroplasticity). Examination of cognitive improvement in patients receiving ECT is complicated by the fact that memory difficulties, especially retrograde amnesia, are a clear side effect of the treatment (Sackeim, 2000). However, many patients show clear cognitive improvement, even shortly after treatment (Sackeim *et al*, 1992).

A few studies likewise show improvement in memory and other cognitive functions in depressed patients after pharmacological treatment. An early study found improvement in memory with treatment with the monoamine oxidase inhibitor (MAOI) moclobemide, which was superior to that of the adrenergic agonist viloxazine or the tetracyclic antidepressant maprotiline (Allain *et al*, 1992). The lack of anticholinergic effects of moclobemide was cited as a potentially important contributor to this difference; the anticholinergic effects of many older antidepressants, especially the tricyclics, may worsen cognitive function and mask any improvement produced by improvement of depression or enhancement of neuroplasticity. A more recent study found improvements in verbal memory after treatment of depressed patients with fluoxetine (Vythilingam *et al*, 2004); another found improvements in memory and attention in patients with late-onset depression after treatment with either fluoxetine or reboxetine (Gallassi *et al*, 2006). The absence of a placebo-treated control group makes it problematic to assign a causal role to the pharmacological treatment in these studies. More studies of the improvement in memory and other cognitive functions that may attend antidepressant treatment are clearly warranted.

As described above, stress can lead to atrophy of both hippocampus and PFC; morphological change in both regions is seen in patients with depression (MacQueen *et al*, 2003; Stockmeier *et al*, 2004). An ideal antidepressant treatment would both prevent this atrophy and, by stimulation of neurotrophic mechanisms, reverse it once it has occurred. No large longitudinal studies have been reported that might evaluate the ability of currently available antidepressants to accomplish this. Some studies examining hippocampal volume in patients with a long history of depression find a correlation with the amount of time spent symptomatically ill, suggesting that successful treatment and symptom reduction may halt a deteriorative process (Shah *et al*, 1998; Sheline *et al*, 1999; MacQueen *et al*, 2003). However, other studies have not found such a correlation (Bremner *et al*, 2000). There is one report that antidepressant treatment reverses the hippocampal volume reduction in PTSD patients and improves declarative memory (Vermetten *et al*, 2003). Additional longitudinal studies will be required to further examine the effects of antidepressant treatment on hippocampal volume in subjects with MDD.

Antidepressants Enhance Learning and Memory in Animal Models

Investigations of the effect of antidepressants on LTP have produced mixed results, with some studies reporting increases in LTP with antidepressant treatment, some decreases, and some with no effects. However, closer examination, comparing effects in subfields of hippocampus (ie dentate gyrus *vs* CA1 pyramidal cell layer) and/or types of antidepressants (tricyclic *vs* nontricyclic SSRIs), reveals more consistency.

In the dentate gyrus, where high-frequency stimulation of the perforant pathway projection to granule cells is used to stimulate LTP, both chronic ECS and chemical antidepressant treatment increase LTP (Stewart and Reid, 2000; Levkovitz *et al*, 2001). One of these studies (Stewart and Reid, 2000) found that chronic ECS or SSRI (fluoxetine) administration increases baseline field potentials in the dentate gyrus. *In vitro* LTP was reduced; this was interpreted as representing a ceiling effect, resulting from prior induction of plasticity by ECS or fluoxetine. The other study reports that either desipramine or mianserin administration results in increased LTP of dentate gyrus (Levkovitz *et al*, 2001). It is interesting to speculate that this increased potential for plasticity in the dentate could result from an increased number of newborn granule cells, which are known to have greater potential for neuroplasticity (Toni *et al*, 2007; Tashiro *et al*, 2007).

In contrast, most early studies of CA1 pyramidal cells report that chronic antidepressant treatment decreases LTP (Massicotte *et al*, 1993; O'Connor *et al*, 1993; Von Frijtag *et al*, 2001). However, these early studies were limited to tricyclic antidepressants (ie imipramine, triimipramine), which have substantial anticholinergic properties that could oppose other effects on plasticity. More recent reports, using antidepressant medications with less anticholinergic effect, have suggested that chronic administration of an SSRI or an atypical antidepressant (tianeptine) increases LTP and blocks the stress-induced impairment of LTP and enhancement of LTD in CA1 (Vouimba *et al*, 2006; Holderbach *et al*, 2007). Chronic SSRI administration has been reported to have similar effects on hippocampal-PFC circuits, reversing a stress-induced impairment of LTP and enhancement of LTD (Rocher *et al*, 2004). Together these studies indicate that chronic antidepressant treatment increases cellular plasticity in the dentate gyrus, and there is some evidence that SSRI antidepressants have a similar effect in on CA1, as well as block the effects of stress on this subpopulation of hippocampal neurons.

Much less is known about the influence of antidepressant treatments on behavioral models of learning and memory. Chronic administration of fluoxetine or venlafaxine, a mixed action reuptake inhibitor, is reported to improve performance in the Morris water maze, a spatial learning and memory model (Nowakowska *et al*, 2000, 2003, 2006), although another study found that fluoxetine did not influence performance in this task (Stewart and Reid, 2000). Chronic imipramine or tianeptine were not effective in the Morris water maze (Nowakowska *et al*, 2000, 2003), although another study found that chronic amitriptyline prevents age-induced impairments in learning and memory (Yau *et al*, 2002). This latter study also found a decrease in circulating corticosterone levels in antidepressant-treated rats that could contribute to the observed improvement in learning and memory. Tianeptine, but not fluoxetine, has been reported to improve discrimination performance in a radial maze task (Jaffard *et al*, 1991). Finally, chronic imipramine, but not paroxetine, has recently been reported to impair spatial working memory in a radial arm maze task (Naudon *et al*, 2007). Clearly, additional studies are needed to further test the influence of different classes of antidepressants in a standardized manner on behavioral models of learning and memory to fully characterize the influence of these agents.

Antidepressant Treatment Enhances Structural Plasticity and Neurogenesis

Increasing evidence suggests that, in addition to enhancing functional neuroplasticity, antidepressants produce structural plasticity. This is observed at several different levels, including numbers of synapses, spines, dendrites, and even numbers of cells.

At the smallest scale, antidepressant treatment has been reported to increase the number of synapses, determined by electron microscopy (Hajszan *et al*, 2005). This study examined the influence of fluoxetine administration of different durations in ovariectomized rats. As few as 5 days of fluoxetine treatment increases the number of synapses in the CA1 pyramidal cell layer, while longer treatment (14 days) also produced a similar increase in the CA3 pyramidal cell layer. Another study found that chronic administration of a tricyclic antidepressant (amitriptyline) blocked the decrease in spine density in dentate gyrus, CA3 and CA1 cell layers that results from olfactory bulbectomy, a widely used model of depression-like behaviors (Norrholm and Ouimet, 2001; in this study, amitriptyptyline alone did not produce an increase in spine density). Although still preliminary, these labor-intensive studies provide evidence for altered structural plasticity at the levels of both synapse and spine density.

More studies have also been conducted at the level of dendritic morphology in the hippocampus. As described above, McEwen and colleagues have demonstrated that chronic stress (intermittent daily immobilization for 3 weeks) decreases the number and length of apical dendrites of CA3 pyramidal cells in the hippocampus (Watanabe *et al*, 1992; McEwen, 1999). This reduction in dendritic length and complexity is blocked or reversed by chronic administration of an atypical antidepressant (tianeptine), but not by a typical SSRI (fluoxetine; Magariños *et al*, 1999). Additional studies are needed to further test the influence of different classes of antidepressants on dendrite morphology in the hippocampus, both alone and in conjunction with exposure to stress.

Another level of structural plasticity that has received a great deal of attention is the regulation of new cell birth or neurogenesis in the hippocampus. These studies demonstrate that chronic antidepressant administration increases neurogenesis in the adult hippocampus (Malberg *et al*, 2000; reviewed in Warner-Schmidt and Duman, 2006). The increase in neurogenesis is observed with different classes of antidepressants, including SSRIs, selective norepinephrine reuptake inhibitors (SNRIs), MAOIs, atypical antidepressants, and ECS. The neurogenic action of antidepressants requires chronic treatment (14–21 days), with the exception of ECS, which increases neurogenesis 3 days after a single seizure. Antidepressants increase different aspects of neurogenesis, including the rate of proliferation (Malberg *et al*, 2000) and the survival of newborn neurons (Nakagawa *et al*, 2002a). Activation of the cAMP-CREB cascade increases neurogenesis, implicating this pathway in the neurogenic actions of antidepressants (Nakagawa *et al*, 2002b). BDNF is also required for antidepressant regulation of the survival of newborn neurons, though not the proliferation (Sairanen *et al*, 2005).

Establishing the causal role of neurogenesis in the behavioral actions of antidepressants has been challenging, as it is technically difficult to functionally perturb the new neurons without simultaneously disrupting other aspects of behavior or hippocampal function. Evidence to date, however, suggests that the induction of neurogenesis is required for antidepressant action. A casual role for neurogenesis in behavioral change requires that a response to antidepressants be dependent on chronic treatment, because it takes several weeks for newborn neurons to differentiate and mature into functional neurons; such a delayed mechanism of action is consistent with the typical delayed therapeutic response to antidepressants. Two paradigms that are dependent on long-term antidepressant administration are novelty-suppressed feeding and chronic unpredictable stress. These models differ from other standard antidepressant screening paradigms, such as the forced swim and tail suspension tests that respond to acute or short-term antidepressant treatments. An initial study found that blockade of cell proliferation by irradiation blocked the actions of antidepressants in novelty-suppressed feeding and chronic unpredictable stress paradigms (Santarelli *et al*, 2003). In addition, 5-HT1A mutant mice, in which SSRI induction of neurogenesis is blocked, show an attenuated antidepressant response (Santarelli *et al*, 2003). Recent studies using another a genetic model to ablate cells that express GFAP, which includes neural precursors, have confirmed these effects (Rene Hen, personal communication).

Effects of Antidepressant Treatment on Glutamatergic Neurotransmission

Just as stress has been found to alter glutamatergic neurotransmission in ways that can contribute to neuronal atrophy and even cell death (Sapolsky, 2000, 2003), antidepressant treatments can modulate glutamate neurotransmission in neuroprotective ways. Indeed, agents that directly modulate neurotransmission hold promise as novel antidepressants (reviewed in Bleakman *et al*, 2007; Pittenger *et al*, 2007; Witkin *et al*, 2007).

Several lines of evidence suggest that established antidepressants can directly modulate glutamatergic neurotransmission. For example, tricyclic antidepressants directly block the NMDA receptor pore at micromolar concentrations (Reynolds and Miller, 1988). Chronic antidepressant treatment alters the conformation of the NMDA receptor, suggesting some form of longer-term compensatory change (reviewed in Paul and Skolnick, 2003). Such actions of antidepressants on the NMDA receptor may represent a mechanism whereby they can influence the mechanisms of neuroplasticity at the synaptic level.

Antidepressant drugs can also affect AMPA receptor trafficking. The investigational antidepressant riluzole, which was developed for the treatment of amyotrophic lateral sclerosis (Miller *et al*, 2007) but has recently been found to hold promise in the treatment of depression (Zarate *et al*, 2004; Sanacora *et al*, 2007), illustrates this point particularly well. Riluzole reversibly attenuates AMPA-mediated synaptic currents in cultured cells (Albo *et al*, 2004). Both rilulzole and the anticonvulsant lamotrigine, which also has antidepressant properties, increase the surface expression of AMPA subunits GluR1 and GluR2, suggesting an effect on the regulated AMPA receptor trafficking that underlies the conversion of silent to active snapses (Du *et al*, 2007). More conventional antidepressants, such as fluoxetine, can regulate the phosphorylation state and thereby the function of AMPA receptors (Svenningsson *et al*, 2002). These effects of antidepressants that target other molecules and pathways have led to the proposal that direct modulators of AMPA function, or AMPAkines, can function as antidepressants; and substantial evidence supports this idea (reviewed in Witkin *et al*, 2007).

A striking recent finding that emphasizes the interaction between antidepressants and glutamatergic neurotransmission is the rapid antidepressant effect of the NMDA antagonist ketamine. This startling effect was first observed in a small study designed to test the psychotomimetic properties of ketamine in depressed patients (Berman *et al*, 2000) and was more recently replicated in a larger study (Zarate *et al*, 2006). As in the case of increased glutamate after chronic stress, this effect is initially counterintuitive: NMDA activation is trophic and enhances neuroplasticity, so NMDA blockade might be expected to worsen cellular damage. Two observations may make sense of this apparent conundrum. As noted above, synaptic and extrasynaptic NMDA receptors have contrasting effects on neuroplasticity and cellular survival. It is likely that subanesthetic doses of

an NMDA antagonist have a preferential effect on extrasynaptic NMDA receptors, both because the higher-affinity NR2B-containing receptors may be more prevalent in the extrasynaptic space and because the ambient glutamate concentration with which the NMDA antagonist must compete is much lower. In addition, *in vivo* evidence from rats suggests that, again at subanesthetic concentrations, ketamine may preferentially block NMDA receptors on GABAergic interneurons and thereby paradoxically increase synaptic glutamate tone, at least in the frontal cortex (Moghaddam *et al*, 1997). This possibility is supported by the observation that NMDA receptor antagonists increase the expression of BDNF, and activity-dependent gene expression (Metsis *et al*, 1993), and increase adult hippocampal neurogenesis (Gould and Cameron, 1997). Appropriately dosed ketamine may therefore simultaneously decrease activation of extrasynaptic NMDA receptors and enhance glutamate tone at synaptic NMDA receptors, producing a net pro-neuroplasticity effect (reviewed in Pittenger *et al*, 2007).

ANTIDEPRESSANTS INCREASE NEUROPLASTICITY-RELATED SIGNALING PATHWAYS

Overlap between the molecular actions of synaptic plasticity and those targeted by antidepressants provided some of the earliest and strongest evidence for mechanistic overlap between the two phenomena. These studies demonstrate that some of the key signaling components identified as critical regulators of LTP and synaptic plasticity are also regulated by antidepressants and are required for the cellular and behavioral actions of antidepressant treatments.

Antidepressants Upregulate the cAMP-PKA-CREB Cascade

Evidence from a number of different studies has demonstrated that antidepressant treatments upregulate the cAMP signal transduction pathway. This includes increased levels of Gαs coupling to adenylyl cyclase in the hippocampus and frontal cortex and resulting elevation of cAMP production in response to chronic administration of different classes of antidepressants (reviewed in Donati and Rasenick, 2003). Levels of PKA are also reported to be upregulated by chronic administration of different classes of antidepressants, including tricyclics, MAOIs, and ECS (Nestler *et al*, 1989; Perez *et al*, 1989). Levels of PKA are increased in particulate fractions, and subcellular fractionation studies demonstrate increases in both the nuclear (Nestler *et al*, 1989; Tiraboschi *et al*, 2004b) and microtubule fractions (Perez *et al*, 2000). The increases in nuclear PKA levels are more consistent with SNRI than SSRI antidepressants, and vary somewhat depending on the brain region examined (PFC *vs* hippocampus) and type of enzyme activity (basal *vs* cAMP-stimulated) in different studies.

Studies demonstrating an increase in nuclear levels of PKA also suggest that the actions of antidepressant treatments could involve the regulation of transcription factors, such as CREB. Early studies provided support for this hypothesis, demonstrating that chronic administration of different classes of antidepressants, including SSRI and SNRI agents, MAOIs, and ECS, increases the expression and function of CREB in the PFC and hippocampus (Nibuya *et al*, 1996; Frechilla *et al*, 1998; for reviews see Tardito *et al*, 2006; Blendy, 2006). These studies demonstrate that chronic, but not acute, antidepressant treatment increases levels of CREB mRNA and immunoreactivity, as well as levels of CRE binding in the hippocampus. Subsequent studies have also demonstrated that the phosphorylation and transcriptional activity of CREB is increased by chronic antidepressant treatment (Thome *et al*, 2000; Tiraboschi *et al*, 2004b). Analysis of CREB and nuclear localization of several protein kinases in the same study indicates that PKA is less likely to account for the induction of CREB phosphorylation than CAMKIV and MAPK, although a role for PKA cannot be completely excluded (Tiraboschi *et al*, 2004b).

Regulation of CREB is likely to be important in antidepressant responses in experimental animals. Viral expression of CREB in the hippocampus produces antidepressant effects in behavioral models of despair and antidepressant response, including the forced swim test and learned helplessness model (Chen *et al*, 2001a, b). Studies of mutant mice have reported that CREB hypomorphic mice have normal antidepressant responses in the FST (Conti *et al*, 2002); this discrepancy may result, in part, from adaptive changes in these knockout mice from partial CREB knockout throughout the brain and throughout development. Drugs that more directly activate the cAMP-CREB cascade, such as the cAMP-specific phosphodiesterase type IV (PDE4) inhibitor rolipram, produce antidepressant effects in behavioral models (reviewed in O'Donnell and Zhang, 2004). The cAMP-CREB cascade also increases adult hippocampal neurogenesis (Nakagawa *et al*, 2002a, b), which, as described above, has been implicated in the actions of antidepressant treatment (Santarelli *et al*, 2003; Duman, 2004).

In humans, there may be a link between genetic polymorphisms in the CREB gene and major depression (Zubenko *et al*, 2003). A recent study also suggested an association between a CREB polymorphism and anger expression (which may relate to suicide risk) in men with depression (Perlis *et al*, 2007). Post-mortem studies suggest that reduced CREB function may contribute to clinical depression, and that its upregulation may also be an important component of antidepressant response in humans. CREB expression in temporal cortex is decreased in depressed suicide subjects (Dowlatshahi *et al*, 1998; Odagaki *et al*, 2001; Dwivedi *et al*, 2003); CREB phosphorylation has also been reported to be reduced in post-mortem tissue (Yamada *et al*, 2003). In addition, CREB is upregulated by pre-mortem antidepressant treatment in post-mortem tissue (Dowlatshahi *et al*, 1998), as well as in blood platelets (Koch *et al*, 2002). While post-mortem studies such as these are particularly challenging, they provide critical evidence that mechanisms elucidated in experimental animals, such as the role of CREB in the antidepressant response, are of clinical relevance in human patients.

These studies provide convincing evidence that the cAMP-PKA-CREB cascade is regulated by antidepressant treatment, and that activation of this pathway can produce

an antidepressant response in behavioral models. The evidence linking these effects to synaptic plasticity is less robust. As described above, the cAMP–PKA–CREB pathway has a central role in many forms of neuroplasticity, and antidepressants can enhance LTP and memory; but this argument for a role for CREB-mediated neuroplasticity is circumstantial. No studies to date have directly tested the role of this pathway in the actions of antidepressants, and future studies will be required to test this hypothesis.

Antidepressants Regulate CaMKII

A number of studies have investigated the regulation of CaMKII by antidepressants. Several studies have reported that chronic, but not acute, antidepressant treatment increases CaMKII enzymatic activity in neuronal cell bodies of the hippocampus, due to an increase in autophosphorylation of CaMKII at Thr^{286} (Popoli *et al*, 1995; Celano *et al*, 2003; Tiraboschi *et al*, 2004a). As described above, phosphorylation at this site leads to Ca^{2+}-independent activation of CaMKII and therefore extended enzymatic activity. Subsequent studies demonstrate that there is also an increase in CAMKII expression, enzymatic activity, and phosphorylation in synaptic vesicles of the hippocampus and PFC after antidepressant treatment (Celano *et al*, 2003), but a decrease in phosphorylation of CaMKII in synaptic terminals and synaptic membranes (Bonanno *et al*, 2005). This apparent contradiction has been resolved by a recent study from the same group, demonstrating that antidepressant treatments (with either an SSRI or an SNRI) cause a redistribution of CaMKII from synaptic membranes to vesicles and a corresponding decrease in membrane-associated synapsin I (Barbiero *et al*, 2007). Since vesicles localized with the synaptic membranes are closely related to the readily releasable pool of glutamate, this redistribution suggests that antidepressant treatment reduces the potential for glutamate release. This is supported by a functional study demonstrating that depolarization-induced release of glutamate is decreased (Bonanno *et al*, 2005).

If this interpretation is correct—that modulation of CaMKII by antidepressants leads to a net decrease in synaptic release of glutamate—antidepressant treatment would decrease the potential for synaptic plasticity, at least via this mechanism. While a reduction in membrane-associated synaptic vesicles could decrease the overall release of glutamate, the resulting effect could be to increase the signal-to-noise ratio such that only salient stimuli lead to synaptic plasticity-related changes in the hippocampus and PFC. An enhanced signal-to-noise ratio may be further enhanced by potentiation of other mechanisms contributing to plasticity through alterations in downstream postsynaptic mechanisms such as cAMP-mediated and MAPK signaling (as reviewed above and below, respectively). Alternatively, the reported upregulation of CAMKII in cell bodies, as opposed to presynaptic terminals, could lead to other types of synaptic plasticity and neuroprotection that also contribute to the actions of antidepressant treatments.

Antidepressants Upregulate the MAPK Cascade

As reviewed above, the MAPK cascade has also been implicated in some forms of long-lasting neuroplasticity. The MAPK pathway is also activated by BDNF and other neurotrophic factors. A number of reports suggest that antidepressants influence the expression or phosphorylation of the kinases in this pathway as well. One study found that chronic administration of different classes of antidepressants increases levels of ERK1 and ERK2 in total homogenates of hippocampus and PFC, although levels of phospho-ERK were not altered (Tiraboschi *et al*, 2004b). This study also reported increases in levels of phospho-ERK1/2 in nuclear fractions, under some conditions, suggesting that ERK signaling may contribute to increased phosphorylation and activation of CREB. However, the situation may be more complicated than this; another study found that fluoxetine administration decreased levels of phospho-ERK1/2 in nuclear and/or cytosolic fractions of hippocampus and PFC, while imipramine increased levels of phospho-ERK in PFC only (Fumagalli *et al*, 2005). Interestingly, chronic administration of an atypical antipsychotic (olanzapine), which has antidepressant efficacy and increases the actions of SSRIs in clinical studies (Nemeroff, 2006), increases levels of ERK1 and ERK2 in PFC fractions (Fumagalli *et al*, 2006).

As in the case of the cAMP/CREB pathway, other lines of evidence suggest that MAPK modulation by antidepressant treatment is likely to play a causal role in the antidepressant response. Agents that inhibit the MAPK pathway increase behavioral despair and helplessness in the forced swim test and learned helplessness paradigms and block the effects of antidepressants in rodents (Duman *et al*, 2007). An earlier study found contrasting effects of MAPK inhibitors, but these effects may be explained by the acute locomotor-activating actions of these agents (Einat *et al*, 2003). Finally, post-mortem studies report that ERK activity and expression are decreased in depressed suicide subjects (Dwivedi *et al*, 2001). More recent studies have reported that ERK5 is also decreased in suicide subjects (Dwivedi *et al*, 2007) and that the upstream kinases responsible for activation of ERK are decreased (Dwivedi *et al*, 2006).

Taken together these studies indicate that antidepressants upregulate the MAPK pathway, opposing the actions of suicide/depression, and that blockade of the MAPK cascade results in despair/helplessness and inhibition of the antidepressant actions in behavioral models. However, there are also conflicting reports on antidepressant regulation of phospho-ERK1/2, depending on the brain region, subcellular fraction, and antidepressant tested.

ANTIDEPRESSANTS UPREGULATE NEUROTROPHIC FACTOR EXPRESSION

Another line of evidence supporting the hypothesis that antidepressant treatment leads to altered neuroplasticity is the regulation of neurotrophic factors by antidepressants. As described above, certain neurotrophic factors, such as BDNF, are regulated by activity; BDNF has been shown to be necessary and sufficient for induction of LTP and performance in some models of learning and memory (reviewed in Pang and Lu, 2004). Furthermore, BDNF is critical to numerous forms of neuroplasticity, and is reduced by chronic stress, as reviewed above. We now

review the evidence that antidepressant treatment increases BDNF and other trophic factors.

Antidepressant Treatment Increases the Expression of BDNF

Chronic antidepressant administration increases the expression of BDNF in the hippocampus and PFC (Nibuya *et al*, 1995; reviewed in Duman and Monteggia, 2006); this effect contrasts with the inhibition of BDNF by chronic stress, as reviewed above. Increased expression of BDNF is observed with different classes of antidepressants, including SSRI, SNRI, MAOI, atypical agents, and ECS. The induction of BDNF is dependent on chronic treatment for 2–3 weeks and is pharmacologically specific: other types of psychotropic drugs do not increase BDNF in the hippocampus and PFC.

There have been a number of conflicting studies, reporting no change or even decreased BDNF expression. These discrepancies are most likely due to differences in the time course or dose of antidepressant tested, or the time after the last treatment (reviewed in Duman and Monteggia, 2006). Since BDNF expression is also decreased by stress and increased by neuronal activity, the individual experimental conditions (eg housing, treatment) are critical for the outcome of these studies.

Roles for BDNF in depression and antidepressant responses are supported by several additional lines of evidence. First, levels of BDNF are decreased in the brains of depressed patients and increased in patients receiving antidepressant treatment at the time of death (Chen *et al*, 2001b; Dwivedi *et al*, 2003; Karege *et al*, 2005). Surprisingly, levels of BDNF in serum of depressed subjects are also decreased; this decrease is reversed by antidepressant treatment, suggesting that it may prove to be a useful, relatively noninvasive biomarker of the depressed state (Karege *et al*, 2002; Shimizu *et al*, 2003; reviewed in Duman and Monteggia, 2006).

Second, BDNF infusions produce an antidepressant response in behavioral models, including the forced swim and learned helplessness paradigms (Siuciak *et al*, 1997; Shirayama *et al*, 2002; Hoshaw *et al*, 2005); and the response to antidepressant treatment is blocked in mice with forebrain-specific impairment of either BDNF or its receptor, TrkB (Saarelainen *et al*, 2003; Monteggia *et al*, 2004). Conditional BDNF mutant mice also display an increase in depression-like behavior in the forced swim and sucrose preference tests, although these effects are specific to female mice (Monteggia *et al*, 2007).

Third, a recent clinical study has reported that a BDNF polymorphism (val66met), when combined with the S allele of the 5-HT transporter, increases the risk for depression in children exposed to trauma (Kaufman *et al*, 2006). The met allele decreases the processing and release of BDNF and has been linked to reduced episodic memory and hippocampal function in humans (Egan *et al*, 2003). The same allele produces a striking anxiety phenotype when introduced into mice (Chen *et al*, 2006).

Together, these studies provide strong support for the hypothesis that reduced BDNF expression contributes to depression-like behavior in animal models and may lead to similar effects in humans, and that antidepressant treatment increases or reverses this deficit. These findings are consistent with the hypothesis that BDNF-induced neuroplasticity contributes to the actions of antidepressants, although it is also possible that other BDNF actions (such as neuroprotection) also play a role.

Antidepressant Treatment Increases the Expression of VEGF

Recent studies have provided evidence that another trophic factor, VEGF, contributes to the actions of stress and antidepressant treatments. Previous studies have demonstrated that VEGF is regulated by neuronal activity and that VEGF increases hippocampal LTP and synaptic transmission (Cao *et al*, 2004). We have recently reported that chronic antidepressant administration, including SSRI, SNRI, and ECS, increases the expression of VEGF mRNA and protein in the hippocampus (Newton *et al*, 2003; Warner-Schmidt and Duman, 2007). As is the case with BDNF, this increase is opposite to the stress-induced decrease in VEGF expression in the hippocampus (Heine *et al*, 2005). VEGF infusions into the lateral ventricles increase neurogenesis and produce antidepressant responses in four different behavioral models, including those responsive to short- (forced swim and learned helplessness) and long-term antidepressant treatments (sucrose preference and novelty-induced hypophagia). In contrast, blockade of VEGF signaling through one of its receptors, VEGF-R2 (also known as Flk-1), blocked the behavioral and neurogenic effects of antidepressants in all four behavioral models (Warner-Schmidt and Duman, 2007).

The results of these studies suggest that VEGF is necessary and sufficient for the behavioral and neurogenic actions of antidepressants. Moreover, the results demonstrate that VEGF contributes to the actions of antidepressants in both short- and long-term responses. It is possible that the rapid effects of VEGF and antidepressants are mediated by regulation of neuroplasticity and synaptic transmission, while the more long-term effects occur via regulation of neurogenesis. Further studies will be required to more completely delineate the cellular mechanisms underlying the actions and interactions of VEGF and antidepressants.

It is striking that multiple neurotrophins have now been implicated in antidepressant action. Indeed, the list may not end here—there is evidence that insulin-like growth factor-1 and fibroblast growth factor-2 are involved in stress, depression, and antidepressant responses (Duman and Monteggia, 2006). There are several possible explanations for this apparent redundancy. First, multiple trophic factors may provide redundancy for neuroplasticity and neuroprotection—critical neuronal functions. However, complete redundancy of the different factors is not supported by data, suggesting that BDNF and VEGF are individually necessary, not just sufficient, for antidepressant responses. It is possible that the different trophic factors exert different, complementary actions, in addition to functions that have some overlap. Additional studies will be needed to fully characterize the interactions of these neurotrophic/growth factor systems.

LIMITATIONS OF THE NEUROPLASTICITY HYPOTHESIS

The neuroplasticity hypothesis suggests that impaired mechanisms of neuroplasticity are a core pathophysiological feature of MDD, that chronic stress is an important causal factor in the development of this impairment, and that antidepressant treatments act, at least in part, through mitigation of impaired mechanisms of plasticity. This hypothesis unifies much clinical and preclinical data, which we have sought to summarize above. However, the hypothesis also has important limitations.

One that has received attention recently is that alterations of neuroplasticity in certain brain regions produce a pro-depressive effect. For example, expression of CREB in the nucleus accumbens increases behavioral despair and helplessness in the forced swim and learned helpless paradigms, and CREB inhibition has an antidepressant effect (Pliakas *et al*, 2001; Newton *et al*, 2002). Similarly, increased expression of BDNF in the mesolimbic dopamine system produces a pro-depressive effect in the forced swim test (Eisch *et al*, 2003) and social defeat stress models of depression (Berton *et al*, 2006). These studies indicate that neuroplasticity in the mesolimbic dopamine circuit can produce effects that are opposite to the antidepressant effects observed in the hippocampus.

Neuroplasticity in the amygdala may likewise work contrary to antidepressant effects, though here the argument is more circumstantial. Chronic stress and glucocorticoid treatment increase dendritic branching and synaptic connectivity in the amygdala, perhaps paralleling the increased size of the amygdala reported in some neuroimaging studies of depressed patients. It seems likely that these plastic events contribute to the development of a depressive state, rather than contributing to antidepressant response.

This suggestion raises the concerning possibility that novel therapeutic strategies aimed at the enhancement of neuroplasticity may have unintended pro-depressant effects through their impact on the nucleus accumbens or other structures outside the hippocampal system that has informed most of our discussion. Early studies suggest that the predominant effect of activating neuroplasticity-associated signaling systems is an antidepressant response. Systemic administration of rolipram, which activates the cAMP-CREB cascade, produces an antidepressant effect in behavioral models (O'Donnell and Zhang, 2004). Similarly, intraventricular infusions of BDNF produce an antidepressant response in the forced swim test (Hoshaw *et al*, 2005). Despite these promising results, further studies in a variety of behavioral models are needed to fully characterize the global effects of activation of neuroplasticity-associated pathways.

RELEVANCE OF ENHANCEMENT IN NEUROPLASTICITY TO BEHAVIORAL MODELS OF DEPRESSION

Although enhanced neuroplasticity is considered a desirable adaptation, the relationship with the actions of antidepressants is not readily interpretable. Are the enhancements in neuroplasticity we have reviewed part of an important pathway that contributes to antidepressant effects? Are they a consequence of altered mood state or homeostasis of modulatory neurotransmitters or hormone systems? Or is the association of enhanced neuroplasticity with antidepressant effect an epiphenomenon—suggestive of shared underlying mechanisms, perhaps, but not necessarily indicative of a causal relationship between the two phenomena?

The nature of the behaviors in rodents that are widely used to model aspects of depression and have proven validity for predicting antidepressant response may shed some light on this question. Most of the behaviors used to assay antidepressant effect in rodents—learned helplessness, the forced swim test, and the tail suspension test, for example—are models of behavioral despair and coping. Animals are placed in an adverse circumstance from which it is difficult or impossible to escape, and they enter a behavioral state of passivity in which they no longer attempt to do so. It may be that enhancements in neuroplasticity, and the corresponding increased capacity to adapt and learn, lead to an enhanced potential repertoire of behaviors or capacity to explore new escape options in these adverse circumstances, and thus reduces the tendency to enter such a state of behavioral despair. This interpretation predicts that enhanced neuroplasticity is, indeed, causally important for reduced depression-like behaviors, at least in models of behavioral despair. It is to be hoped that as our understanding of the complex relationships between stress, depression, and neuroplasticity grows, the functional interrelationship of one to another will become more clear. Even at this early point, the extensive mechanistic parallels between these disparate phenomena suggest a deep causal connection.

SUMMARY AND CONCLUSIONS

The molecular mechanisms of antidepressant response overlap with those of neuroplasticity to a striking degree. We have described three levels of neuroplasticity in which this parallel can be seen. Synaptic plasticity (including morphological change in dendritic spines and other concomitants of synaptic connections) has been well characterized in many brain regions, most prominently the hippocampus. Many of the molecular mechanisms of synaptic plasticity are induced by antidepressants; again, the hippocampus presents the best-characterized example of this fact. Parallels are seen both with the mechanisms of short-term plasticity—such as the insertion of AMPA receptors into the membrane and the modulation of CaMKII—and with those of long-term plasticity—such as the activation of transcription factors such as CREB and the induction of plasticity-enhancing genes such as BDNF.

Parallels are also seen at the level of dendritic morphology. Increases in dendritic branching can be induced by enriched environments (van Praag *et al*, 2000), growth factors, and other neuroplasticity-inducing manipulations. Similar increases in dendritic length and complexity can be induced by antidepressant treatment. Finally, neurogenesis represents a more recently appreciated but profound mechanism of neuroplasticity, permitting the insertion of new neurons into the dentate gyrus of the adult animal. Here, too, neurogenesis is stimulated both by plasticity-inducing stimuli (such as environmental enrichment, exercise, and electrical stimulation) and by antidepressant treatments.

While it is difficult to examine these mechanisms in tissue from depressed humans, evidence exists for impairment of neuroplasticity in major depression. Molecular concomitants of certain aspects of synaptic plasticity—such as expression and phosphorylation of the transcription factor CREB—are reduced in post-mortem tissue from depressed subjects. Depression leads to shortening and reduced complexity of dendritic trees, in the hippocampus and the PFC. It remains to be determined whether neurogenesis is reduced in patients with major depression (the one study published to date was negative; Reif *et al*, 2006); but neurogenesis has been shown to occur in the human hippocampus in adulthood (Eriksson *et al*, 1998), and thorough examination of whether it is reduced in major depression is certainly warranted by the strength of the preclinical evidence.

Stress is well established to contribute to the development of major depression in susceptible individuals. It is likely that any comprehensive account of the pathophysiology of mood disorders will include an important causal role for psychological and physiological stress. It is therefore striking that chronic stress, too, opposes many forms of neuroplasticity. As reviewed above, chronic stress reduces synaptic plasticity and dendritic spines, reduces the length and complexity of dendrites, and impairs neurogenesis.

The convergence of these literatures—neuroplasticity, antidepressant response, and the consequences of chronic stress—on an overlapping set of molecular and cellular mechanisms is increasingly apparent and suggests a deep connection between these three phenomena. Further explorations and better understanding of these relationships is likely to point the way toward a deeper understanding of affective disorders and, it is to be hoped, toward novel treatments. This will include the development and use of novel strategies for imaging structural and molecular pathways in human subjects *in vivo*, as well as post-mortem and genetic studies to identify and define the exact alterations underlying the disruption of neuroplasticity in depressed subjects. The findings demonstrating altered neuroplasticity have already provided novel targets for drug development and future studies will continue to identify and refine the information for further development of more effective therapeutic interventions.

DISCLOSURE/CONFLICT OF INTEREST

RSD is a consultant for Taisho Pharmaceuticals and Psychogenics, has received funding for investigator initiated research from Lilly, Organon, Pfizer, Sepracor, and Roche, and has received speaker honorariums from Lilly, Pfizer, Sepracor, Roche, Bristol-Myers-Squibb and Wyeth-Ayerst. ARTICLE

Stress-induced generalization of negative memories is mediated by an extended hippocampal circuit

Lynn Y. Ren[1]✉, Mariah A. A. Meyer[1], Viktoriya S. Grayson[1], Pan Gao[1], Anita L. Guedea[1] and Jelena Radulovic[1,2,3]✉

Memories of negative experiences exert important control of behavior in the face of actual or anticipated threat. Sometimes, however, this control extends to non-threatening situations, a phenomenon known as overgeneralization of negative memories. Overgeneralization is a reliable cognitive phenotype of major depressive disorder, generalized anxiety disorder, and post-traumatic stress disorder. We therefore sought to develop an animal model to study stress-induced generalization of negative memories (SIG) and determine its dependence on the episodic-like memory circuit. We found that male and female mice, which were trained to differentiate a threatening from neutral context, exhibited robust SIG in response to subsequent social stress. Using chemogenetic circuit manipulations during memory retrieval, we demonstrated that both excitatory afferents to the dorsal hippocampus (DH) from the ventral tegmental area (VTA), and excitatory efferents from the DH to the retrosplenial cortex (RSC) contribute to SIG. Based on the known roles of these projections, we suggest that (1) by targeting subcortical VTA circuits that provide valence signals to the DH, stress prioritizes the retrieval of negative over neutral memories, and (2) by forwarding such information to the RSC, stress engages cortical mechanisms that support the retrieval of general relative to specific memory features. Altogether, these results suggest that various components of the extended hippocampal circuit can serve as treatment targets for memory overgeneralization.

INTRODUCTION

Generalized anxiety disorder (GAD), major depressive disorder (MDD), and post-traumatic stress disorder (PTSD) are often accompanied by debilitating cognitive symptoms, which impede recovery from these disorders, often persist after antidepressant treatment of other symptoms, and increase the likelihood of relapse [1–7]. Additionally, they precede and predict associated affective symptoms [1, 8, 9]. A recurrent cognitive symptom across MDD, GAD, and PTSD is overgeneralization of negative memories [10–20], which involves excessive control of behavior by negative memories, even in neutral situations. Stress can promote generalization of negative memories [21, 22]; however, the neurobiological and circuit mechanisms underlying this effect are not well-understood. Notably, current knowledge of memory generalization focuses largely on processes related to the encoding [23–27] of new memories in a manner that promotes their generalization, whereas much less is known about memory retrieval processes that act upon consolidated memories [28, 29].

The dorsal hippocampus (DH) is crucial for mediating valence-memory integration, memory formation, memory retrieval, and memory generalization [30–38]. These functions partly rely on vGlut2-positive afferents from the ventral tegmental area (VTA) that provide a valence signal to the DH [33] and DH vGlut1-positive efferents to the retrosplenial cortex (RSC), which contribute to the long-lasting representations of episodic-like memories [39–45]. We therefore hypothesized that these components of the extended hippocampal circuit might contribute to stress-induced generalization (SIG).

Chronic social stressors, such as social defeat stress and social instability stress, induce a spectrum of anxiety-like and depressive-like behaviors in rodents [46–54]. Here, we demonstrate that exposure to subacute versions of these social stressors induces SIG in both male and female mice that is not associated with stress-induced anxiety-like and depressive-like behavioral phenotypes. Using chemogenetic manipulations, we show that SIG occurs at memory retrieval and is mediated by circuits involved in processing negative valence (VTA to DH) and long-term memory representation (DH to RSC).

METHODS

Mice

We performed these experiments using male and female C57BL/6J mice, vGlut1-Cre, and vGlut2-Cre mice. Wild-type C57BL/6J mice were purchased from Harlan (Indianapolis, IN) and wild-type CD-1 aggressor male mice were purchased from Charles Rivers (Wilmington, MA). All other mouse lines were obtained from Jackson Laboratory (Bar Harbor, ME). The vGlut1-Cre knockin mice, also known as Slc17a7-IRES2-Cre-D and Vglut1-IRES2-Cre-D, express Cre-recombinase in glutamatergic neuron cell bodies containing vesicular glutamate transporter 1 (vGlut1). The vGlut2-Cre knockin mice, also known as Slc17a6tm2(cre)Lowl and Vglut2-IRES-Cre, express Cre-recombinase in glutamatergic neuron cell bodies containing vesicular glutamate transporter 2 (vGlut2). Heterozygous mice were

backcrossed with wild-type C57BL/6J for six generations in our facility to achieve offspring with a genetic identity closer to the C57BL/6J strain. The colony was subsequently expanded by homozygous breeding and confirmed by genotyping using primers and protocols posted on the Jackson Laboratory website.

All mice were 8 weeks old at the beginning of the experiments. The mice were maintained under standard housing conditions (12/12 h light–dark cycle with lights on at 7 a.m., temperature 20–22 °C, humidity 30–60%) in our satellite behavioral facility. Randomization was performed by assigning similar numbers of littermates to the different treatment conditions. Behavioral experiments were performed by an experimenter blind to drug treatments and experimental groups. All animal procedures used in this study were approved by the Northwestern University IACUC and complied with federal regulations set forth by the National Institutes of Health.

Contextual fear conditioning and generalization

Contextual fear conditioning was performed in an automated system (TSE Systems, Chesterfield, MO) [45]. Context A (Cxt A) was scented with ethanol, had a metal grid floor, was rectangular in shape, and had dim room lighting. Context B (Cxt B) was scented with acetic acid, had a smooth plastic floor, was oval in shape, and had brighter room lighting. Cxts A and B were cleaned with 70% ethanol and 1% acetic acid, respectively, between mice. Mice were pre-exposed to Cxt A and Cxt B for 3 min each. Exposures to these contexts were spaced 3 h apart, with half of the mice in each experimental group being exposed to Cxt A first and the other half being exposed to Cxt B first. 24 h later, mice underwent 3 days of contextual fear conditioning. Each day consisted of 3 min of exposure to the conditioning context, followed by a footshock (2 s, 0.7 mA, constant current). Twenty-four hours after the last day of contextual fear conditioning, mice were tested for memory generalization by placing them into Cxt B for 3 min, as adapted from Xu et al. [55]. Freezing was scored every 10 s during context exposures and expressed as a percentage of the total number of observations during which the mice were motionless. Mice were also tested for memory retrieval by returning them to Cxt A for 3 min. The Generalization Index was adapted from discrimination indices that are commonly used to assess context discrimination [24, 55] and was calculated as follows:

$$0.5 - [(\text{Cxt A freezing} - \text{Cxt B freezing})/(\text{Cxt A freezing} + \text{Cxt B freezing})]$$

A higher generalization index indicated increased generalization.

Mice were exposed to social defeat stress or social instability stress (see below for details) 24 h after pre-stress memory tests. Twenty-four hours after the completion of social defeat stress or social instability stress, mice underwent post-stress memory tests.

Social defeat stress and social instability stress

Social defeat stress (SDS) [51] was conducted in male mice by placing an "intruder" (the experimental mouse) into the home cage of an aggressive "resident" (CD-1 male mouse) for 5 min. Intruder mice were returned to their own home cage after 5 min. Experimental mice underwent social defeat once per day for 4 consecutive days and were exposed to a different aggressive resident mouse each day.

Social Instability Stress (SIS) [52, 53] was conducted in female mice by alternating mice between 72 h of housing with three other unfamiliar females and 24 h of isolation. During each round of 72-h housing, the mice were exposed to three new cage-mates. This continued for a total of 11 days.

Elevated plus maze test, open-field test, sucrose preference test, and light–dark emergence test

During the sucrose preference test (SPT), mice were allowed to freely drink from two 50 mL graduated bottles. One bottle contained 1% sucrose (vol/vol) in distilled water, and the other bottle contained distilled water alone. Mice underwent 48 h of habituation to these bottles, during which bottle locations were alternated after 24 h. After habituation, sucrose and water consumption were measured every 24 h for a total of 96 h. The mass of liquid consumed was measured to a resolution of ±0.01 g. Water and sucrose bottle locations were alternated after every measurement to eliminate position bias.

During the open-field test (OFT), mice were placed in the center of a 50 × 50 cm platform for 5 min. The time spent in the center region (25 × 25 cm), velocity, and total distance traveled were measured using automatic video tracking software (VideoMot, TSE Systems). The platform was cleaned with 0.5% ammonium between mice.

During elevated plus maze (EPM) testing, mice were placed in the center of a plus shaped platform with two open arms and two closed arms for 5 min. The dimensions of each arm were 30 × 5 cm. The time spent in the open and closed arms, velocity, and total distance traveled were measured using automatic video tracking software (VideoMot). The platform was cleaned with 0.5% ammonium between mice.

During light–dark emergence (LDE), mice were placed into a dark box (10 ×10 x 10 cm) in the center of a 50 ×50 cm platform and the latency for the mice to emerge from the dark box was measured. The platform was cleaned with 0.5% ammonium between mice.

Stereotaxic surgeries and infusions of viral vectors and drugs

Mice were anesthetized with 1.2% tribromoethanol (vol/vol; Avertin) for viral vector intracranial infusion and cannula implantation. AAV8-hSyn-DIO-GFP (Addgene 50457, Addgene, Watertown, MA), AAV8-hSyn-DIO-mCherry (Addgene 50459), or AAV8-hSyn-DIO-hM4D(Gi)-mCherry (Addgene 50475) were bilaterally infused into the VTA (3.4 mm posterior, ±0.5 mm lateral, 4.3 mm ventral to bregma) or DH (1.8 mm posterior, ±1 mm lateral, 2.25 mm ventral to bregma). Infusions were performed using an automatic pump controller (Micro4-WPI, Sarasota, FL) connected to a microsyringe (Hamilton, Reno, NV). Viral vectors were infused into the VTA at a volume of 0.35 µL per site or into the DH at 0.5 µL per site, at a titer $\geq 3 \times 10^{12}$ vg/mL, over 2 min. Syringes were left in place for 5 min to allow for virus diffusion. Mice were allowed 4 weeks for virus expression before behavioral experiments.

Bilateral 26-gauge guide cannulas (Plastics One, Roanoke, VA) were placed in the DH (1.8 mm posterior, ±1.0 mm lateral, 2.25 mm ventral to bregma) or RSC (1.8 mm posterior, ±0.4 mm lateral, 0.75 mm ventral to bregma). Mice were allowed 1 week of recovery before behavioral experiments. Clozapine-N-Oxide (CNO; Sigma, St. Louis, MO; 0.3 µg/mL in 0.7% DMSO and 99.3% aCSF (vol/vol)) or vehicle (Veh; 0.7% DMSO and 99.3% aCSF (vol/vol)) was infused through the cannulas (0.25 µL per side into DH or 0.20 µL per side into RSC over 30 s) 30 min prior to context retrieval or the generalization test. After the completion of behavioral testing, mice were intracardially perfused and cannula placements and virus spread were confirmed by immunohistochemical analysis of mCherry signals.

Immunohistochemistry and immunofluorescence

Mice were anesthetized with an i.p. injection of 240 mg/kg Avertin and transcardially perfused with ice-cold 4% paraformaldehyde in phosphate buffer (pH 7.4). Brains were removed and post-fixed for 24 h in the same fixative solution and then immersed for 24 h each in 20% and 30% sucrose in phosphate buffer. Brains was frozen and 50 µm sections were cut for use in free-floating immunohistochemistry with primary antibodies against mCherry (1:16000, chicken polyclonal, ab205402, abcam, Cambridge, MA) or tyrosine hydroxylase (1:2000, mouse monoclonal, Immunostar 22941, Immunostar, Hudson, WI) and biotinylated goat anti chicken IgG or biotinylated goat anti mouse IgG secondary antibodies (1:200, Vector Laboratories, Burlingame, CA). Signals were amplified using ABC-HRP (1:100, Vector Laboratories) and visualized with TSA tetramethylrhodamine (1:62.5, Perkin Elmer, Waltham, MA) using fluorescent microscopy.

Quantification and statistical analyses

Statistical analyses were performed using Graphpad (San Diego, CA). All statistical tests were two-sided. Data used for analyses included: (1) mice with virus expression in the DH or VTA of 50% or more of the mean number of DH or VTA-infected neurons across all experiments, (2) mice with detectable VTA-originating terminals in the DH or DH-originating terminals in the RSC, and (3) mice with correctly implanted cannulas in the DH or RSC. For the behavioral studies, two-way RM ANOVA using either (1) context and treatment as factors or (2) context and stress as factors was used to determine differences in conditioning or altered context freezing between groups, as well as the effect of stress on conditioning context and altered context freezing. Significant *F*-values were followed by post-hoc multiple comparisons using Tukey's or Sidak's test. To calculate the generalization index, the same mice were exposed to both Cxt A and Cxt B. Differences in the generalization index were also determined for treatment (CNO or Veh) or stress (Pre-Stress vs Post-Stress) using two-tailed Mann–Whitney test or Wilcoxon matched-pairs signed rank test. Differences in behavioral measures during EPM, OFT, LDE, or SPT paradigms were determined for stress (No Stress vs Stress) using two-tailed Students T test. Statistical differences were considered significant for all *p*-values <

RESULTS

Stress induces generalization in male and female mice

In the absence of stress (pre-stress retrieval, Fig. 1A), male mice exhibited significantly more freezing in Cxt A compared to in Cxt B (Fig. 1B), indicating weak generalization. After SDS, however, mice no longer showed significant differences in freezing between Cxt A and Cxt B due to significantly higher freezing in Cxt B (Fig. 1B). Accordingly, the generalization index was significantly higher post-stress compared to pre-stress (Fig. 1C). To control for the possibility that this effect was due to an overall increase in fear due to stress, rather than interaction between stress and memory systems, we repeated the same experiment without delivery of footshocks in the conditioning context (Fig. 1D). Under this condition, we found no increase in freezing in Cxt A or Cxt B after SDS, suggesting that SDS alone does not increase freezing (Fig. 1E). Additionally, to control for potential generalization of memories over time, we repeated the same experiment with a 4-day waiting period instead of SDS (Fig. 1F) and also found no increase in freezing in Cxt B (Fig. 1G). Finally, we found that pre-stress retrieval tests were not necessary for the SIG phenotype to develop (Fig. S1), and the order of Cxt A or Cxt B testing during memory retrieval did not affect SIG (Fig. S2). Together, these results suggest that SIG arises from the effects of stress on memory systems.

Next, we sought to study SIG in female mice. SIS was performed on female mice in lieu of SDS, as male CD-1 mice used as aggressors in SDS do not reliably show aggression towards female mice. Similar to male mice, we found that after SIS (Fig. 2A), female mice exhibited significantly higher freezing in Cxt B and a significantly higher generalization index, as compared to before SIS (Fig. 2B, C). Accordingly, mice no longer had significant differences in freezing between Cxt A and Cxt B after SIS (Fig. 2B). To control for the possibilities that the effect was due to an overall increase in fear or due to generalization of negative memories over time, we repeated the same experiment without delivery of footshocks in Cxt A (Fig. 2D) or with a 11-day waiting period instead of SIS (Fig. 2F). We found no increase in freezing in Cxt A or B after stress under either of these conditions (Fig. 2E, G). As in our previous study, the order of Cxt A or Cxt B testing did not affect SIG (Fig. S2). Altogether, these results show that social stress can be a strong trigger of SIG in both male and female mice.

Stress-induced generalization is not associated with anxiety-like or depressive-like behaviors in male and female mice

SDS and SIS have been shown to induce depression-like and anxiety-like behaviors when applied over 10 days and 28 days, respectively [46–54]. We therefore examined whether these behaviors could be related to SIG, which was induced by subacute versions of these stressors in this study. In both male and female mice, we found no significant differences between stressed and non-stressed mice (Figs. S3 and S4), in their latency to emerge in the LDE paradigm or sucrose preference in the SPT. We also found no significant differences in time spent in the open arms in the EPM or time spent in the center region in the OFT, despite the trends towards significance in these two tests in female mice (Fig. S4). Altogether, these results demonstrate that SIG is not associated with anxiety-like and depression-like behaviors that are induced by chronic SDS and SIS.

vGlut2-expressing VTA projections to DH contribute to stress-induced generalization

We recently showed that vGlut2 + VTA afferents to the DH provide a negative valence signal that is sufficient to trigger fear reinstatement after extinction [33]. We therefore examined

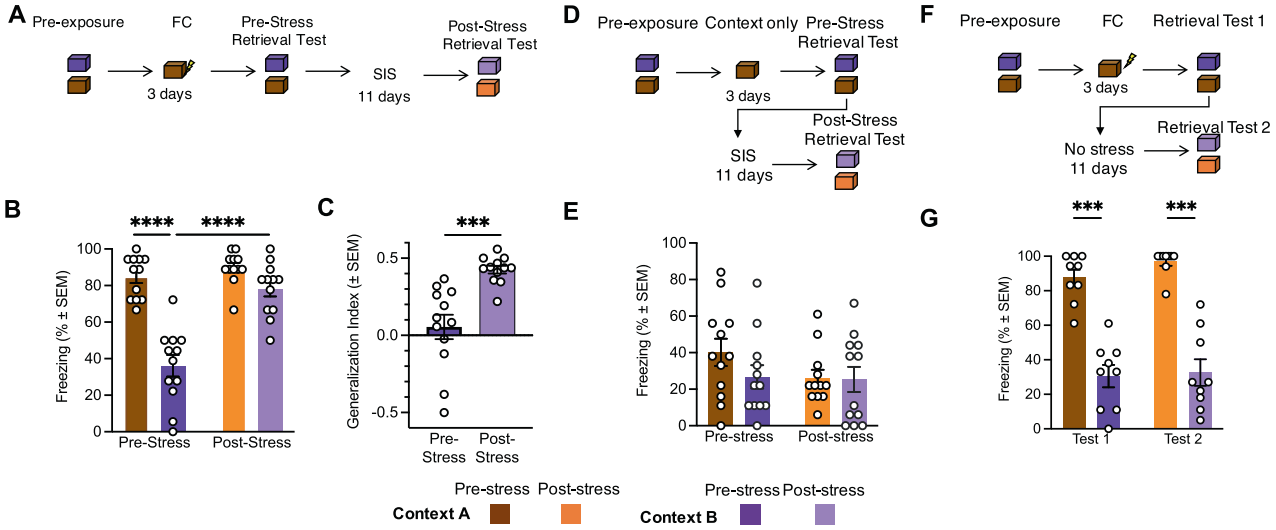

Fig. 2 Stress induces generalization of negative memories in female mice. A Behavioral schematic for SIG performed in female mice and shown in **B**, **C**. **B** Freezing in Context A and Context B in female mice before and after SIS. Two-way RM ANOVA. Factor: Stress, $F(1,11) = 34.81$, $p = 0.0001$. Factor: Context, $F(1,11) = 72.44$, $p < 0.0001$. Factor: Stress x Context, $F(1,11) = 28.66$, $p = 0.0002$. Post-hoc Tukey, $^{****}p < 0.0001$. $n = 12$ mice per group. **C** Generalization index (see methods for formula) in female mice. Note that mice were exposed to context without footshock. **E** Freezing in Context A and Context B after SIS in the absence of FC. Two-way RM ANOVA. Factor: Stress, $F(1,9) = 0.2024$, $p = 0.6634$. Factor: Context, $F(1,9) = 1.802$, $p = 0.2124$. Factor: Stress x Context, $F(1,9) = 0.006574$, $p = 0.9372$. $n = 10$ mice per group. **F** Behavioral schematic for **G**. Note that mice were exposed to FC but not SIS. **G** Freezing in Context A and Context B after FC in the absence of SIS. Two-way RM ANOVA. Factor: Timepoint, $F(1,8) = 1.776$, $p = 0.2193$. Factor: Context, $F(1,8) = 285.1$, $p < 0.0001$. Factor: Timepoint x Context, $F(1,8) = 2.570$, $p = 0.1476$. Post-hoc Tukey $^{****}p < 0.001$. $n = 9$ mice per group.

whether these projections, by providing a negative valence signal during retrieval of Context B, might also contribute to SIG. In agreement with our previous work [33], GFP-positive terminals in DH were observed after injection of AAV8-hSyn-DIO-GFP into the VTA of vGlut2-Cre mice (Fig. 3A, B). To determine the role of these projections in SIG, we infused AAV8-hSyn-DIO-hM4Di-mCherry into the VTA of vGlut2-Cre male and female mice. Both male (Fig. 3E, F) and female mice (Fig. 3G, H) that received infusion of CNO into DH after stress and before memory retrieval showed significantly reduced generalization indices and Cxt B freezing compared to mice that received infusion of Veh (Fig. 3E–H). Additionally, CNO-infused mice showed significant differences between freezing in Cxt A and Cxt B, whereas Veh-infused mice did not (Fig. 3E, G for males and females, respectively). To rule out the possibility that this effect was due to off-target effects of CNO in the DH, we infused control virus (AAV8-hSyn-DIO-mCherry) into the DH of vGlut1 + mice, as vGlut1 is the predominant glutamatergic neuron subtype in the DH. In these mice, we found no differences in Cxt A or B freezing in mice that received CNO vs. Veh (Fig. S5), suggesting that SIG was not caused by CNO in the absence of hM4Di. To explore the role of these projections in generalization in the absence of stress, male and female mice underwent three days of fear conditioning but were not exposed to social stress afterwards. CNO or Veh was infused before memory retrieval tests. In this case, CNO-infused male and female mice showed no differences in freezing in Cxt A or Cxt B and showed no difference in generalization index compared to Veh-infused mice (Fig. S6). Altogether, these results suggest that VTA vGlut2 + projections to the DH contribute to SIG.

vGlut1-expressing DH projections to RSC contribute to stress-induced generalization

vGlut1 + and vGlut2 + DH projections to RSC are the predominant hippocampal efferents to the neocortex required for the formation (vGlut1 + and vGlut2 +) and retrieval (vGlut1 +) of context memories [39]. We next determined whether these projections also participate in SIG. First, we infused AAV8-hSyn-DIO-mCherry into DH and observed their projections in ventral RSC in vGlut1-Cre (Fig. 4A) and vGlut2-Cre mice (Fig. S7). In agreement with our previous work [39], we found robust mCherry + axon terminals in ventral RSC (Fig. 4B and Fig. S7). Next, we infused AAV8-hSyn-DIO-hM4Di-mCherry into the DH of vGlut1-Cre and vGlut2-Cre mice. After stress, we found that, in both male and female vGlut1-Cre mice (Fig. 4F–H), but not vGlut2-Cre male mice (Fig. S7), infusion of CNO into the RSC before memory retrieval tests led to a significant reduction in the generalization index and Cxt B freezing compared to the Veh-infused group. Additionally, in both male and female vGlut1-Cre mice (Fig. 4E, G), infusion of CNO before memory retrieval tests led to a significant difference in freezing between Cxt A and Cxt B after stress that did not occur in the Veh-infused group. Such effects were not seen in vGlut2-Cre mice (Fig. S7). These results suggest that SIG-relevant information was also conveyed from DH to RSC through vGlut1 + glutamatergic projections.

DISCUSSION

Here, we present a preclinical model for studying SIG by exposing mice to subacute social stress after training them to discriminate aversive from neutral contexts. While we cannot directly establish sex-specific effects due to differences in the social stressors used, it is noteworthy that despite this limitation, different social stressors similarly engaged the extended DH circuit in generating SIG. Furthermore, SIG was not associated with anxiety-like and depressive-like phenotypes that are typically reported after longer exposures to SDS or SIS [46–54]. This suggests that SIG is a separate phenotype and raises an interesting possibility that SIG may be an early cognitive change that ultimately contributes to increased negative affective states.

Memory generalization is often viewed as a problem of memory encoding [23–26], occurring either due to the inability to form sufficiently non-overlapping representations of contexts (e.g., Context A and B) [56], or due to the predominant encoding of general rather than specific features of individual contexts [24].

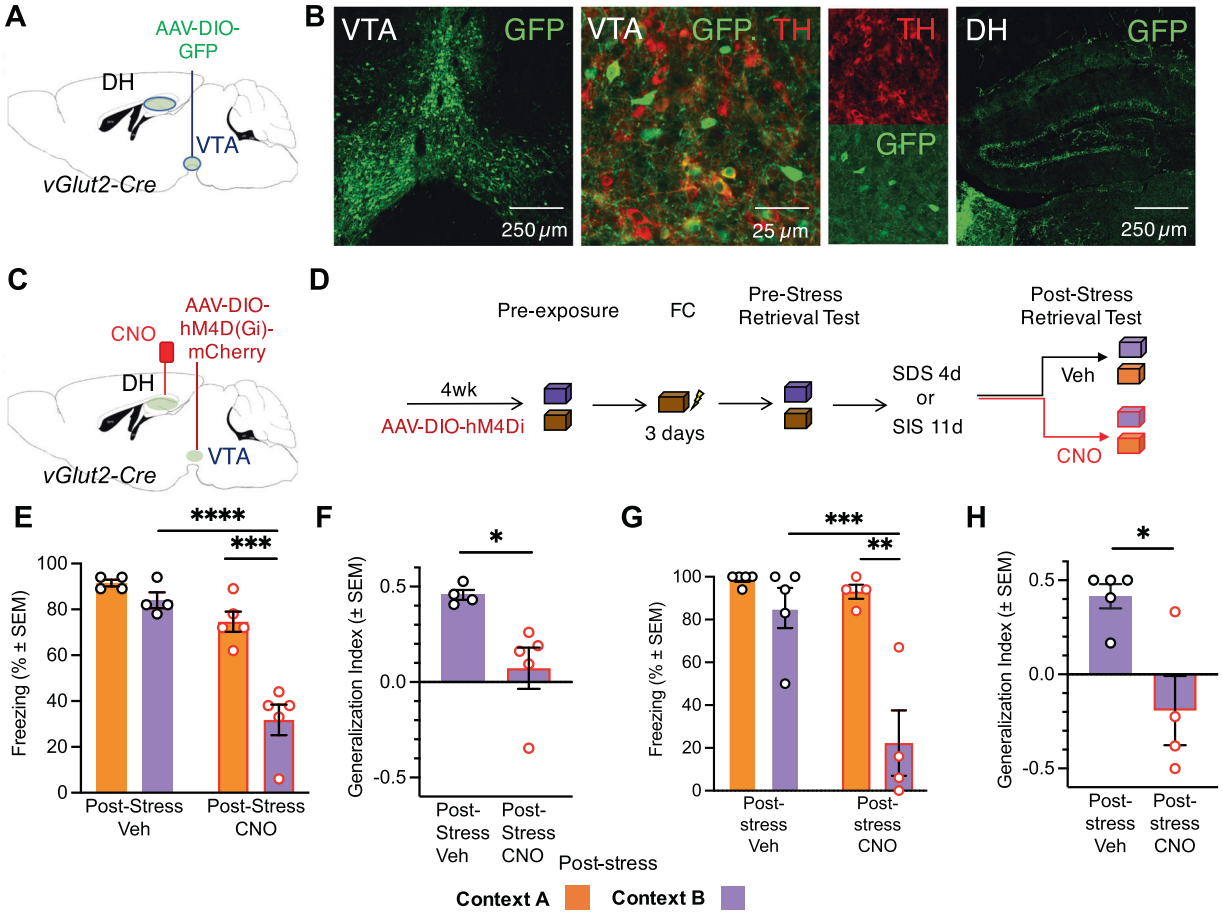

Fig. 3 Inhibition of vGlut2 + VTA projections to DH reduces stress-induced generalization in male and female mice. However, such encoding mechanisms are not likely to contribute to SIG, given that several circuit manipulations that we applied at retrieval reversed generalization, thereby revealing that mice were able to encode the contexts in a manner that allowed them to be distinguished from each other. Recent work however, including empirical research and computational models, has emphasized that generalization is also controlled by memory retrieval mechanisms [28, 29]. Our findings show that these mechanisms are highly susceptible to social stress, which may act on the components of the extended hippocampal circuit related to both negative valence [33] and memory [39]. These findings are based on usage of chemogenetic circuit manipulations that we previously extensively validated for their ability to silence both neurons [57] and terminals [33, 39] using slice electrophysiology.

The densest DH glutamatergic projections from VTA terminate in the dentate gyrus and CA2/CA3. There are several mechanisms by which these afferents could contribute to generalization. Based on our recent work [33], we posit that VTA projections to DH provide a negative valence signal that results in reinterpretation of aspects of Context B at retrieval. At the cellular level, this can occur by reactivation of cell ensembles that encode general memory features [24] or by activation of CA3 recurrent loops that support memory generalization [58–60] by VTA afferents, or both.

DH glutamatergic projections to RSC primarily stem from the subiculum. Thus, it is likely that there are one or more intermediary intrahippocampal synapses between VTA glutamatergic projections to DH and DH glutamatergic projections to RSC. Indeed, integration and transmission of information through these microcircuits may then ultimately activate cortical memory representations, which tend to be less specific and more general than hippocampal representations [61, 62]. Therefore, SIG might also target systems consolidation mechanisms mediated by vGlut1-positive DH projections to RSC to bias retrieval toward general rather than specific context features. It should be noted, however, that the effects of our manipulations of vGlut1-positive DH projections to RSC were modest and did not completely diminish SIG, suggesting that targeting vGlut1-positive DH projections to RSC may not be necessary for the full effect of SIG. Consistent with our previous findings [39] in non-stressed mice, vGlut2 + DH- >RSC projections did not significantly

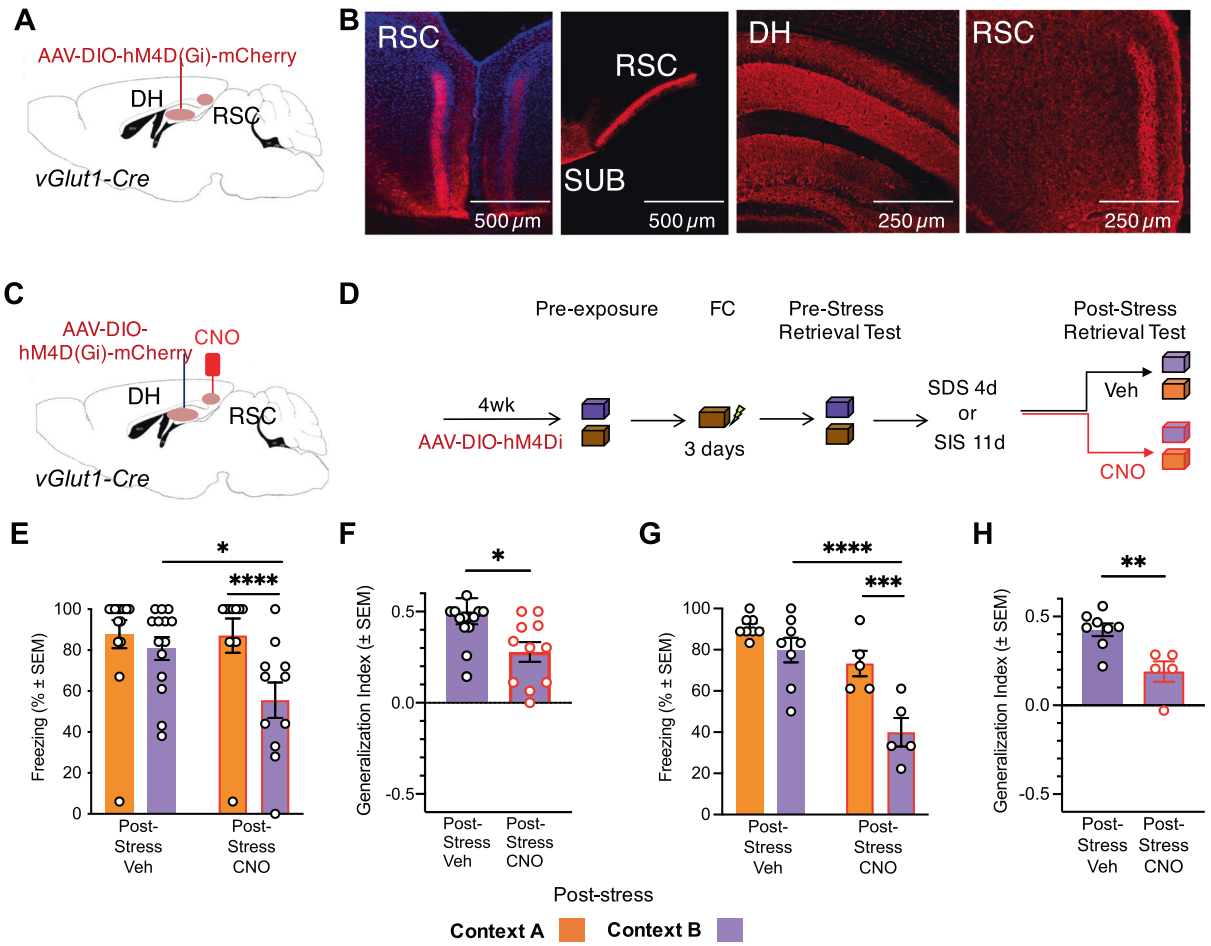

Fig. 4 Inhibition of vGlut1 + DH projections to RSC reduces stress-induced generalization in male and female mice. contribute to the retrieval of recent context memories either in stressed mice, supporting the specificity of our manipulations and the specificity of the effects of stress on individual projections within the extended hippocampal circuit.

The finding that glutamatergic VTA projections to DH and DH projections to RSC play a role in SIG but not negative memory retrieval is very interesting, especially given that our previous work showed that inhibition of vGlut1 + DH to RSC projections before memory retrieval in the conditioning context reduced conditioning context freezing in the absence of stress [39]. This suggests that either stress alters the neurobiology of this circuit so that it is no longer necessary for retrieval of the original memory, or that the stronger training protocol (3 context-shock associations over 3 days) used in this study might lead to a more robust contextual memory that is represented more redundantly in neuronal networks and may thus be less dependent on this circuit than a single context-shock association [63]. Additionally, this more robust fear memory may contribute to a ceiling effect in freezing levels, which may require more widespread manipulations (e.g.,: co-inhibition of several DH afferents or efferents) to observe a behavioral effect. Finally, it cannot be ruled out that mechanisms involved in retrieval of weaker aversive memories are repurposed towards sub-serving generalization during retrieval of strong memories.

Our results are translationally relevant for several reasons. First, we found that SIG is not associated with other anxiety-like and depressive-like behaviors, suggesting that SIG may be a separate cognitive change independent of affective symptoms, much like overgeneralization is a cognitive phenotype in MDD, GAD, and PTSD that can persist after treatment of affective symptoms. This also leads to the interesting possibility that SIG precedes other anxiety-like and depressive-like behaviors in a similar way as overgeneralization precedes and predicts affective symptoms of MDD, GAD, and PTSD [1, 8, 9]. Second, our finding that SIG occurs during memory retrieval may inform retrieval-based therapeutics for overgeneralization, which may be more clinically effective than

encoding-based therapeutics for overgeneralization. This is primarily due to the fact that patients have already encoded many negative memories by the time they present for treatment. Thus, SIG may be a promising model for researching therapeutic strategies for the prevention and the development of MDD, GAD, and PTSD. Finally, the inclusion of female mice in this study is crucial as MDD, GAD, and PTSD affect significantly more women than men in the United States as well as globally [64–67]. Altogether, these results provide a rodent model to study SIG, elucidate a neural circuit mediating SIG, and provide a framework for future therapeutics targeting overgeneralization.

FUNDING AND DISCLOSURES

The human brain has often been viewed as outstanding among mammalian brains: the most cognitively able, the largest-than-expected from body size, endowed with an overdeveloped cerebral cortex that represents over 80% of brain mass, and purportedly containing 100 billion neurons and 10× more glial cells. Such uniqueness was seemingly necessary to justify the superior cognitive abilities of humans over larger-brained mammals such as elephants and whales. However, our recent studies using a novel method to determine the cellular composition of the brain of humans and other primates as well as of rodents and insectivores show that, since different cellular scaling rules apply to the brains within these orders, brain size can no longer be considered a proxy for the number of neurons in the brain. These studies also showed that the human brain is not exceptional in its cellular composition, as it was found to contain as many neuronal and non-neuronal cells as would be expected of a primate brain of its size. Additionally, the so-called overdeveloped human cerebral cortex holds only 19% of all brain neurons, a fraction that is similar to that found in other mammals. In what regards absolute numbers of neurons, however, the human brain does have two advantages compared to other mammalian brains: compared to rodents, and probably to whales and elephants as well, it is built according to the very economical, space-saving scaling rules that apply to other primates; and, among economically built primate brains, it is the largest, hence containing the most neurons. These findings argue in favor of a view of cognitive abilities that is centered on absolute numbers of neurons, rather than on body size or encephalization, and call for a re-examination of several concepts related to the exceptionality of the human brain.

Keywords: brain scaling, number of neurons, human, encephalization

INTRODUCTION

THE HUMAN BRAIN AS A SPECIAL BRAIN

What makes us human? Is our brain, the only one known to study other brains, special in any way? According to a recent popular account of what makes us unique, "we have brains that are bigger than expected for an ape, we have a neocortex that is three times bigger than predicted for our body size, we have some areas of the neocortex and the cerebellum that are larger than expected, we have more white matter" – and the list goes on (Gazzaniga, 2008). Most specialists seem to agree (for example, Marino, 1998; Rilling, 2006; Sherwood et al., 2006). Since ours is obviously not the largest brain on Earth, our superior cognitive abilities cannot be accounted for by something as simple as brain size, the most readily measurable parameter regarding the brain. Emphasis is thus placed on an exceptionality that is, curiously, not brain-centered, but rather body-centered: With a smaller body but a larger brain than great apes, the human species deviates from the relationship between body and brain size that applies to other primates, great apes included, boasting a brain that is 5–7× too large for its body size (Jerison, 1973; Marino, 1998). Recent efforts to support this uniqueness have focused on finding genetic differences between humans and other primates (reviewed in Vallender, 2008), as well as cellular particularities such as the presence and distribution of Von Economo neurons (Nimchinsky et al., 1999; but see Butti et al., 2009; Hakeem et al., 2009).

To regard the human brain as unique requires considering it to be an outlier: an exception to the rule, whatever that rule is. This makes little sense, however, in light of evolution. If we go to such great lengths to affirm, and teach, that evolution is the origin of diversity in life, and to find trends and laws that apply to kingdoms, phyla and orders as a whole, why then insist that whatever scaling rules apply to other primates must not apply to us? In view of the vexing size inferiority in brain size and of the lack of information about what our brains are actually made of – and how that compares to other brains, particularly those of whales and elephants – resorting to a quest for uniqueness may have seemed as a necessary, natural step to justify the cognitive superiority of the human brain.

Recently, a novel quantitative tool developed in our lab (Herculano-Houzel and Lent, 2005) has finally made the numbers of neurons and non-neuronal cells that compose the brains of various mammals, humans included, available for comparative analysis. This review will focus on such a quantitative, comparative analysis, with emphasis on the numbers that characterize the human brain: what they are, how they have been viewed in the past, and how they change our view of where the human brain fits into the diversity of the mammalian nervous system.

THE HUMAN BRAIN IN NUMBERS

How many neurons does the human brain have, and how does that compare to other species? Many original articles, reviews and textbooks affirm that we have 100 billion neurons and 10 times more glial cells (Kandel et al., 2000; Ullian et al., 2001; Doetsch, 2003; Nishiyama et al., 2005; Noctor et al., 2007; Allen and Barres, 2009), usually with no references cited. This leaves the reader with

the impression that the cellular composition of the human brain has long been determined. Indeed, an informal survey with senior neuroscientists that we ran in 2007 showed that most believed that the number of cells in the human brain was indeed already known: that we have about 100 billion neurons, outnumbered by about 10 times more glial cells – but none of the consulted scientists could cite an original reference for these numbers (Herculano-Houzel and Lent, unpublished observations). Curiously, the widespread concept that neurons represent about 10% of all cells in the human brain might be one of the arguments behind the popular, but mistaken, notion that we only use 10% of our brain (Herculano-Houzel, 2002).

The reason for such lack of references is that indeed there was, to our knowledge, no actual, direct estimate of numbers of cells or of neurons in the entire human brain to be cited until 2009. A reasonable approximation was provided by Williams and Herrup (1988), from the compilation of partial numbers in the literature. These authors estimated the number of neurons in the human brain at about 85 billion: 12–15 billion in the telencephalon (Shariff, 1953), 70 billion in the cerebellum, as granule cells (based on Lange, 1975), and fewer than 1 billion in the brainstem. With more recent estimates of 21–26 billion neurons in the cerebral cortex (Pelvig et al., 2008) and 101 billion neurons in the cerebellum (Andersen et al., 1992), however, the total number of neurons in the human brain would increase to over 120 billion neurons.

As to the 10 times more numerous glial cells in the human brain, that seems to be the case only in subcortical nuclei such as the thalamus (17 glial cells per neuron) and the ventral pallidum (12 glial cells per neuron; Pakkenberg and Gundersen, 1988). In the gray matter of the cerebral cortex, glial cells outnumber neurons by a factor of <2 (Sherwood et al., 2006; Pelvig et al., 2008). Given the relatively small number of glial cells reported for the human cerebellum, where they are outnumbered by neurons by at least 25:1 (Andersen et al., 1992), the only possible explanation for the ubiquitous quote of 10 times more glial than neuronal cells in the entire human brain would be the presence of nearly one trillion glial cells in the remaining structures alone – an unlikely scenario, since these structures represent <10% of total brain mass.

WHY BOTHER WITH CELL NUMBERS?

Across species, the number of neurons and their relative abundance in different parts of the brain is widely considered to be a determinant of neural function and, consequently, of behavior (Williams and Herrup, 1988). Among mammals, those species with the largest brains, such as cetaceans and primates, have a greater range and versatility of behavior than those with the smallest brains, such as insectivores (Jerison, 1985; Marino, 2002). Among birds, those that are larger-brained (corvids, parrots and owls) are also considered the most intelligent (Lefebvre et al., 2004). A recent comparison of several parameters, including brain size, relative brain size, encephalization, conduction velocity and estimated numbers of neurons led two authors to conclude that the "factors that correlate better with intelligence (across species) are the number of cortical neurons and conduction velocity, as the basis for information processing" (Roth and Dicke, 2005). Indeed, within non-human primates, a recent meta-analysis concluded that the best predictor of the cognitive abilities of a species is absolute brain size, not relative size nor encephalization quotient (EQ; Deaner et al., 2007).

However, the correlation between absolute brain size and cognitive abilities breaks down when species of similar brain size are compared across orders. Monkeys, for instance, possess brains that are much smaller than those of ungulates, but the higher cognitive and behavioral flexibility of monkeys over ungulates is anecdotally evident to any observer who compares the ingenious and complex abilities of macaques to those of cows or horses, even though the latter have 4–5× larger brains than macaques. For similar-sized brains, rodents also perform more poorly than primates: With a brain of only 52 g, the behavioral, social and cognitive repertoire of the capuchin monkey is outstanding compared to the capybara, a giant Amazonian rodent (MacDonald, 1981), even though the latter has a larger brain of 75 g. This is reminiscent of the most striking and troubling discrepancy regarding brain size and cognitive abilities: that between humans and larger-brained species such as whales and elephants. If the latter have brains that are up to six times larger than a human brain, why should we be more cognitively able? Answering this question requires a direct examination of the numbers of neurons that compose the brains of humans and other species.

BRAIN AND BODY SCALING: THE TRADITIONAL VIEW

ASSUMPTION 1: BODY SIZE MATTERS

If the smaller size of the human brain compared to elephant and whale brains (**Figure 1**) translates into a smaller number of neurons in the human brain than in the latter, then what makes the human brain outstanding in its cognitive abilities? In the absence of direct estimates of numbers of neurons in these and other species, the search for a neural correlate for human capacities has placed emphasis on the characteristic that most undisputedly places humans above other mammals: the EQ (Jerison, 1973). This measure is based on the observation that, across species, brain size correlates with body size in a way that can be described mathematically with a power function, thus allowing the predicted brain mass to be calculated for any species. EQ indicates how much the observed brain mass of a species deviates from the expected for its body mass: an EQ of 1 indicates that the observed brain mass matches the expected value; an EQ >1 means that brain size in that species is larger than expected for its body mass.

Compared to mammals as a whole, humans have the largest EQ found for any mammal, of between 7 and 8 (Jerison, 1973); even if compared to anthropoid primates only, humans still have an EQ of over 3, a value that is larger than that obtained for any other

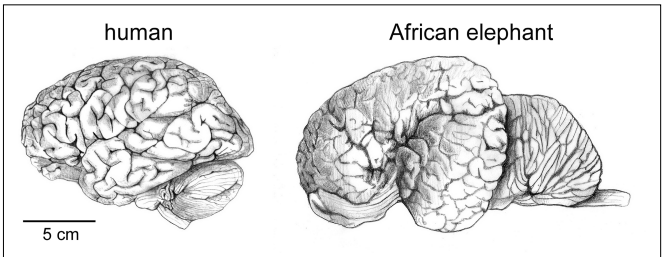

FIGURE 1 |The human brain is not the largest. Brains of a human and of an African elephant are depicted here at the same scale. Drawings by Lorena Kaz based on images freely available from the University of Wisconsin and Michigan State Comparative Mammalian Brain Collections (www.brainmuseum.org).

primate or cetacean (Marino, 1998). The position of the human species as an outlier in the body × brain comparison is made clear if one considers that although gorillas and orangutans overlap or exceed humans in body size, their brains amount to only about one-third of the size of the human brain.

There are, however, several problems with the notion that the explanation for the superior cognitive abilities of the human species lies in its large EQ. For one, it is not obvious how larger-than-expected brain mass would confer a cognitive advantage. In principle, this advantage would rely on the availability for cognitive functions of whatever brain mass exceeds what is necessary to process body-related information. However, according to this notion, small-brained animals with very large EQs should be expected to have more cognitive abilities than large-brained animals with smaller EQs. Capuchin monkeys, for instance, have much larger EQs than gorillas (Marino, 1998), but are outranked by these in cognitive performance (Deaner et al., 2007). Absolute brain mass and number of neurons, left out of the encephalization equation, must clearly be taken into consideration, since the "exceeding number of neurons" in a large brain should necessarily be larger than that in a smaller brain of same EQ (Herculano-Houzel, 2007).

Another problem with the utility of the EQ is that the body–brain mass relationship from which expected brain mass is derived depends on the precise combination of species computed (Barton, 2006; Herculano-Houzel et al., 2007). We have recently found that, compared to the linear brain × body relationship that applies to the primate species in our sample (which consisted of simian and prosimian primates; Herculano-Houzel et al., 2007), the human brain deviates by only 10% from its expected size (Azevedo et al., 2009). This conformity to the body × brain relationship that applies to non-anthropoid primates is consistent with the observation that, like in other non-anthropoid primates, the human brain mass represents about 2% of body mass. Given the sensitivity of EQ to the species included and our finding that the human brain conforms to the scaling rules that apply to other primates (see below), we have suggested that, rather than humans having a larger brain than expected, it is the great apes such as orangutans and, more notably, gorillas that have bodies that are much larger than expected for primates of their brain size (Herculano-Houzel et al., 2007).

This latter possibility of a dissociation between brain and body development in evolution (which might be only circumstantially, and not causally, related) constitutes a final criticism to the usefulness of the EQ as an index of "brain" evolution in comparative studies: indeed, the emphasis on the body-centered EQ overlooks the observation that, compared to other mammalian orders, primate encephalization is the result of a shift in postcranial growth processes, not a modification of brain growth (Deacon, 1997). In the words of Deacon, "if primates have big brains merely because they have small bodies, we cannot presume that this represents an evolutionary trend driven by cognitive demands" (p. 343). In this scenario, however, the human brain exhibits a further modification in that it continues to grow as though in a larger body (Deacon, 1997).

ASSUMPTION 2: BRAIN SIZE MATTERS

Brain size varies across mammals by a factor of approximately 100,000 (Tower, 1954; Stolzenburg et al., 1989). Different mammalian orders have traditionally been pooled together in studies of brain allometry, as if their brains were built according to the same scaling rules (for example, Haug, 1987; Zhang and Sejnowski, 2000).

Comparisons across orders that seem to invalidate the correlation between numbers of neurons and cognitive ability, such as between monkeys and ungulates, or rodents and primates, also bear this hidden caveat: the assumption that brain size relates to number of neurons in the brain in a similar fashion across orders. This assumption, which was justifiable by the lack of direct estimates of the neuronal composition of the brain of different species, is so widespread that it implicitly or explicitly underlies most comparative studies to date (for example, Haug, 1987; Finlay and Darlington, 1995; Barton and Harvey, 2000; Clark et al., 2001). The very concept of encephalization presupposes that not only the brain scales as a function of body size, but that all brains scale the same way, such that the only informative (and sufficient) variable is brain size and its deviation from the expected. However, our quantitative studies on the cellular scaling rules that apply to different mammalian orders have shown that this assumption is invalid and therefore should no longer be applied (see below).

ASSUMPTION 3: PROPORTIONS AND RELATIVE SIZE MATTER

An often cited argument in favor of the uniqueness of the human brain is its relatively large cerebral cortex, which accounts for 82% of brain mass. Within this large cerebral cortex, a relative enlargement of the prefrontal cortex was once considered a hallmark of the human brain, but this view has however been overthrown by modern measurements (Semendeferi et al., 2002). Still, the distribution of cortical mass in humans may differ from that in other primates, endowing particularly relevant regions such as area 10 with relatively more neurons in the human cortex (Semendeferi et al., 2001).

Relative size is supposed to be a meaningful indicator of relative functional importance of a brain structure based on the assumption that it is a proxy for relative number of neurons. For instance, the increase in relative size of the cerebral cortex with increasing brain size simultaneously with no systematic change in the relative size of the cerebellum has been used as evidence that these structures are functionally independent and have been evolving separately (Clark et al., 2001). Such discrepancy would support the popular notion that brain evolution equates with development of the cerebral cortex, which comes to predominate over the other brain structures. However, analysis of absolute, rather than relative, cerebral cortical and cerebellar volumes in the same dataset leads to the opposite conclusion: the coordinated scaling of these volumes, as well as of the surface areas of these structures, would be evidence that the cerebral cortex and cerebellum are functionally related and have been evolving coordinately (Barton, 2002; Sultan, 2002).

As it turns out, however, the underlying assumption that the relative size of a brain structure reflects the relative number of brain neurons that it contains is flawed.

Now that numbers of neurons are available across rodents, primates and insectivores, we find that the cerebral cortex, despite varying in relative size from 42% (in the mouse) to 82% of brain mass (in the human), contains between 13 and 28% of all brain neurons in 15 of 18 species studied, ranging between 13% (in moles) and 41% (in the squirrel monkey; Herculano-Houzel et al.,

2006, 2007; Sarko et al., 2009). Most importantly, this fractional number of neurons in the cerebral cortex relative to the whole brain is not correlated with the relative size of the cerebral cortex (**Figure 2**). Instead, the number of neurons in the cerebral cortex increases coordinately with the number of neurons in the cerebellum (Herculano-Houzel, submitted).

A NEW VIEW: SCALING OF NEURONAL NUMBERS

CELLULAR SCALING RULES FOR RODENT, INSECTIVORE, AND PRIMATE BRAINS

Our group has been investigating the cellular scaling rules that apply to brain allometry in different mammalian orders using the novel method of isotropic fractionation, which produces cell counts derived from tissue homogenates from anatomically defined brain regions (Herculano-Houzel and Lent, 2005). Through the estimation of absolute numbers of neuronal and non-neuronal cells in the brains of different mammalian species and their comparison within individual orders, we have been able to determine the scaling rules that apply to the brains of species spanning a wide range of body and brain masses in rodents (Herculano-Houzel et al., 2006), primates (Herculano-Houzel et al., 2007) and more recently in insectivores (Sarko et al., 2009). A comparative overview of brain mass and total number of neurons for these species can be seen in **Figure 3**.

A recent issue in comparative studies of brain scaling has been the examination of how residual variation in different parameters relate to phylogenetic relationships once shared evolutionary commonalities in body or brain size are accounted for (Harvey and Pagel, 1991; Nunn and Barton, 2000). Although such analyses of independent contrasts are instrumental for identifying evolutionary correlations across taxa while taking into account this phylogenetic nonindependence, they overlook the very issue at hand here: how the size of the brain reflects the number of neurons that it contains, regardless of body size and of any other shared characteristics. For this reason, the analysis reviewed here, referred to as unveiling the "cellular scaling rules" for the brain of different mammalian orders, considers solely how brain size changes as a function of its number of neurons within a given order, irrespective of body size, and without any concerns regarding phylogenenetic effects within that order, or even whether evolution of the extant species has involved an expansion of brain size, a reduction, or both. In the particular case of primates, we have recently extended our analysis to another set of five primate species (Gabi et al., submitted), and found that the same cellular scaling relationships apply to the original dataset (Herculano-Houzel et al., 2007), to the second dataset, and to the combined, extended dataset. This is evidence that the cellular scaling rules considered here from a set of primate species also extend to primates as a whole, and can be used to infer the expected cellular composition of the human brain – even though small variations may occur across species that might, indeed, be due to phylogenetic interdependencies.

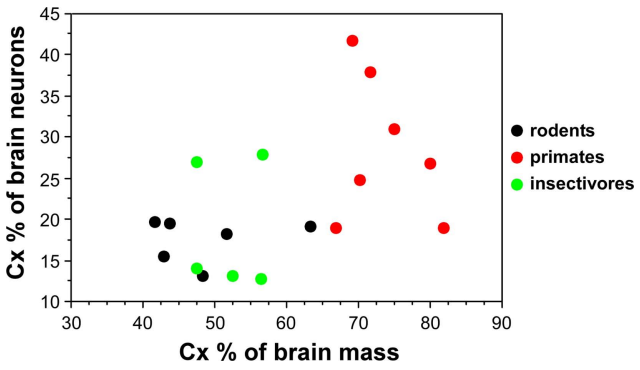

FIGURE 2 | Relative size of the cerebral cortex does not inform about the relative number of neurons in the cortex compared to the whole brain. Each point indicates, for a given species, the average relative cortical mass as a percentage of total brain mass (X-axis) and the average relative number of cortical neurons as a percentage of the total number of neurons in the brain (Y-axis). Data from Herculano-Houzel et al. (2006, 2007); Azevedo et al. (2009); and Sarko et al. (2009).

In the order Rodentia, we find that the brain increases in size faster than it gains neurons, with a decrease in neuronal densities which, in the presence of constant non-neuronal cell densities, implies that average neuronal size increases rapidly as neurons become more numerous (Herculano-Houzel et al., 2006). The increase in numbers of neurons in the cerebral cortex, cerebellum and remaining areas is concurrent with an even greater increase in numbers of non-neurons, yielding a maximal glia/neuron ratio that increases with brain size (Herculano-Houzel et al., 2006). These findings corroborated previous studies describing neuronal density decreasing and the glia-to-neuron ratio increasing with increasing brain size across mammalian taxa (Tower and Elliot, 1952; Shariff, 1953; Friede, 1954; Tower, 1954; Hawking and Olszewski, 1957; Haug, 1987; Reichenbach, 1989; Stolzenburg et al., 1989).

In contrast to rodent brains, which scale hypermetrically in size with their numbers of neurons, primate brain size increases approximately isometrically as a function of neuron number, with no systematic change in neuronal density or in the non-neuronal/neuronal ratio with increasing brain size (Herculano-Houzel et al., 2007). Across insectivore species, on the other hand, the cerebellum increases linearly in size as a function of its number of neurons (as in primates), while the cerebral cortex increases in size hypermetrically as it gains neurons (as in rodents; Sarko et al., 2009). In view of the similar non-neuronal cell densities across species, hypermetric scaling of brain structure mass as a function of its number of neurons implies a concurrent increase in the average neuronal size (which, in the method's definition, includes not only the cell soma but also the entire dendritic and axonal arborizations as well as synapses; Herculano-Houzel et al., 2006). As a consequence of these different cellular scaling rules, shown in **Table 1**, a 10-fold increase in the number of neurons in a rodent brain results in a 35-fold larger brain; in contrast, a similar 10-fold increase in the number of neurons in a primate brain results in an increase in brain size of only 11-fold.

NOT ALL BRAINS ARE CREATED EQUAL: COGNITIVE ABILITIES AND NUMBERS OF NEURONS

The different cellular scaling rules that apply to rodent, primate and insectivore brains show very clearly that brain size cannot be used indiscriminately as a proxy for numbers of neurons in the brain, or even in a brain structure, across orders. By maintaining the average neuronal size (including all arborizations) invariant

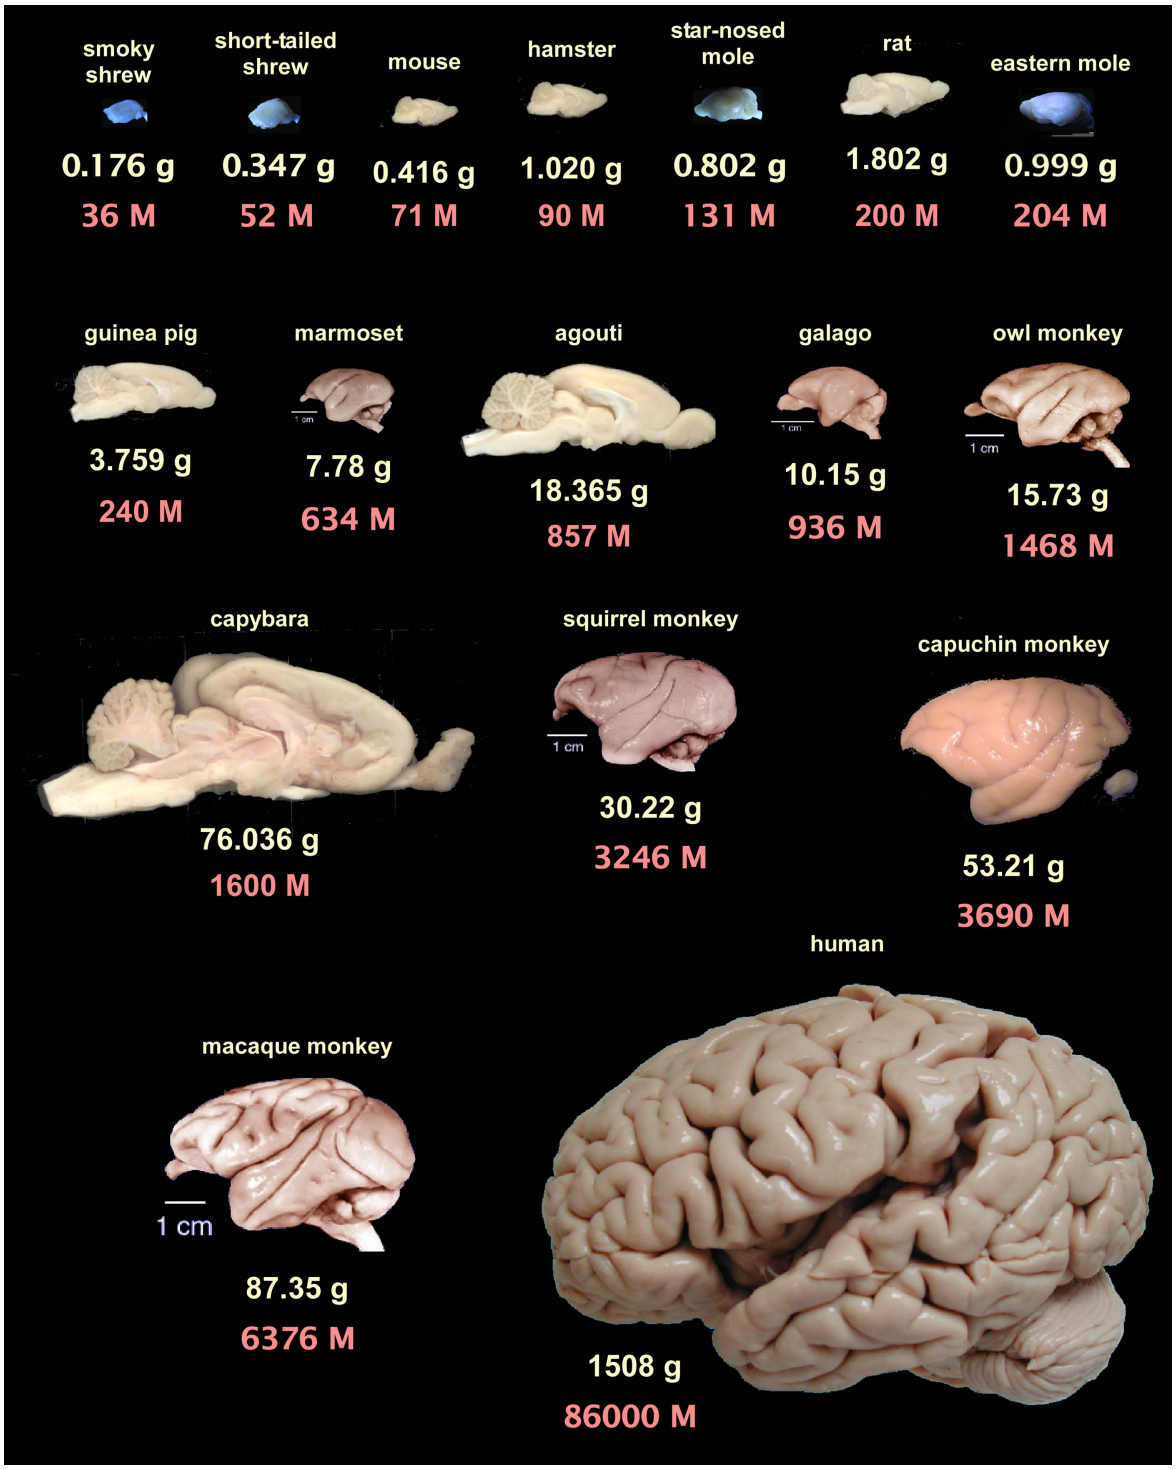

FIGURE 3 | Brain mass and total number of neurons for the mammalian species examined so far with the isotropic fractionator. Brains are arranged from left to right, top to bottom, in order of increasing number of neurons according to average species values from Herculano-Houzel et al., 2006 (rodents), Herculano-Houzel et al., 2007 (non-human primates), Sarko et al., 2009 (insectivores) and Azevedo et al., 2009 (human brain). Rodent brains face right, primate brains face left, insectivore brains can be identified in the figure by their bluish hue (due to illumination conditions). All images shown to the same scale. Primate images, except for the capuchin monkey and human brain, from the University of Wisconsin and Michigan State Comparative Mammalian Brain Collections (www.brainmuseum.org). Insectivore images kindly provided by Diana Sarko, and human brain image by Roberto Lent. Rodent images from the author. Notice that some rodent brains, such as the agouti and the capybara, contain fewer neurons than primate brains that are smaller than them.

as brain size changes, primate brains scale in size in a much more space-saving, economical manner compared to the inflationary growth that occurs in rodents, in which larger numbers of neurons are accompanied by larger neurons.

The cognitive consequences of this difference, which allows primate brains to enjoy the benefits of a large increase in numbers of neurons without the otherwise associated cost of a much larger increase in overall brain volume, can be glimpsed by returning to the comparison between rodents and primates of similar brain size. Now that absolute numbers of neurons can be compared across the similar-sized brains of agoutis and owl monkeys, and of capybaras and capuchin monkeys (**Figure 4**), the expected correlation between cognitive ability and numbers of neurons is actually found to hold: with 1468 million neurons, owl monkeys have almost twice as many neurons in the brain as agoutis (which hold 857 million), and about four times more neurons in the cerebral cortex than the agouti (442 million versus 113 million). Likewise, the capuchin monkey brain has more than twice the number of neurons of the larger-brained capybara (3.7 billion against 1.6 billion), and also about four times more neurons in the cerebral cortex (1.1 billion against 0.3).

The significance of the difference in scaling rules for building brains with large numbers of neurons becomes even more obvious if one considers the expected number of neurons for a generic rodent brain of human-sized proportions, weighing 1.5 kg: such a brain would have only 12 billion neurons, and a much larger number of 46 billion non-neuronal cells. This number of neurons is smaller than the number of neurons estimated to exist in the human cerebral cortex alone (Pakkenberg and Gundersen, 1997; Pelvig et al., 2008), and about seven times smaller than the number of neurons predicted for a 1.5-kg brain built with the scaling rules that apply to primates (see below).

Table 1 | Power law exponents that apply to the scaling of brain mass, or structure mass, as a function of the number of neurons they contain in rodents, insectivores and primates.

	Rodents	Insectivores	Primates
Brain mass × neurons	$M_{BR} \sim N_{BR}^{1.550}$	$M_{BR} \sim N_{BR}^{1.016}$	$M_{BR} \sim N_{BR}^{1.056}$
Cortical mass × neurons	$M_{CX} \sim N_{CX}^{1.744}$	$M_{CX} \sim N_{CX}^{1.520}$	$M_{CX} \sim N_{CX}^{1.077}$
Cerebellar mass × neurons	$M_{CB} \sim N_{CB}^{1.372}$	$M_{CB} \sim N_{CB}^{1.028}$	$M_{CB} \sim N_{CB}^{0.990}$
Remaining areas mass × neurons	$M_{RA} \sim N_{RA}^{1.153}$	$M_{RA} \sim N_{RA}^{0.926}$	$M_{RA} \sim N_{RA}^{1.013}$

Data are from Herculano-Houzel et al. (2006), Sarko et al. (2009) and Herculano-Houzel et al. (2009). Scaling laws for primate brains do not include human values.

THE CELLULAR COMPOSITION OF THE HUMAN BRAIN

The determination of the cellular scaling rules that apply to primate brains (Herculano-Houzel et al., 2007) enabled us to predict the cellular composition of the human brain. According to these rules, a generic primate brain of 1.5 kg should have 93 billion neurons, and 112 billion non-neuronal cells: glial cells, thus, should constitute at most half of all brain cells. This generic primate brain should have a cerebral cortex of about 1.4 kg, containing 25 billion neurons, and a cerebellum weighing 120 g, with 70 billion neurons (**Table 2**).

Establishing whether the human brain indeed conforms to the scaling rules that apply to other primates, however, required determining its cellular composition using the same method. This was accomplished by Azevedo et al. (2009), who found that the adult male human brain, at an average of 1.5 kg, has 86 billion neurons and 85 billion non-neuronal cells – numbers that deviate from the expected by 7 and 24% only. The human cerebral cortex, with an average 1233 g and 16 billion neurons, is slightly

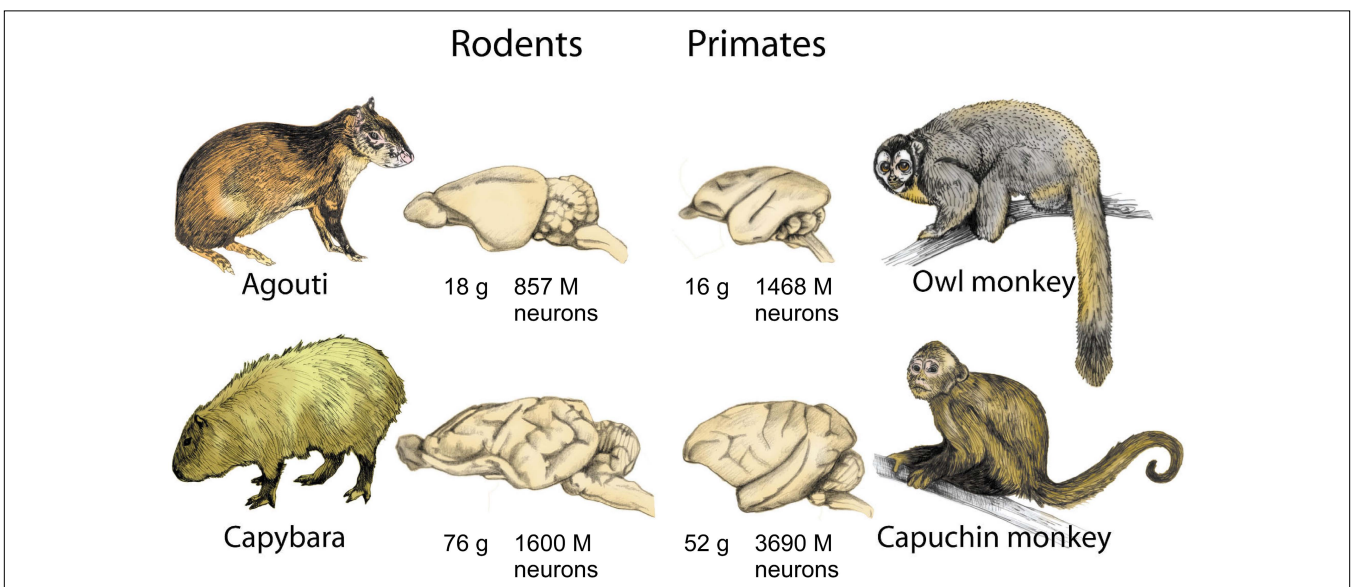

FIGURE 4 | Brain size is not a reliable indicator of number of neurons across orders. Because of the different cellular scaling rules that apply to rodent and primate brains, primates always concentrate larger numbers of neurons in the brain than rodents of a similar, or even larger, brain size. Data from Herculano-Houzel et al. (2006, 2007). Illustration by Lorena Kaz.

Table 2 | Expected values for a generic rodent and primate brains of 1.5 kg, and values observed for the human brain (Azevedo et al., 2009).

	Generic rodent brain	Generic primate brain	Human brain
Brain mass	1500 g	1500 g	1508 g
Total number of neurons in brain	12 billion	93 billion	86 billion
Total number of non-neurons in brain	46 billion	112 billion	85 billion
Mass, cerebral cortex	1154 g	1412 g	1233 g
Neurons, cerebral cortex	2 billion	25 billion	16 billion
Relative size of the cerebral cortex	77% of brain mass	94% of brain mass	82% of brain mass
Relative number of neurons in cerebral cortex	17% of brain neurons	27% of brain neurons	19% of brain neurons
Mass, cerebellum	133 g	121 g	154 g
Neurons, cerebellum	10 billion	61 billion	69 billion
Relative size of the cerebellum	9% of brain mass	8% of brain mass	10% of brain mass

Notice that although the expected mass of the cerebral cortex and cerebellum are similar for these hypothetical brains, the numbers of neurons that they contain are remarkably different. The human brain thus exhibits seven times more neurons than expected for a rodent brain of its size, but 92% of what would be expected of a hypothetical primate brain of the same size. Expected values were calculated based on the power laws relating structure size and number of neurons (irrespective of body size) that apply to average species values for rodents (Herculano-Houzel et al., 2006) and primate brains (Herculano-Houzel et al., 2007), excluding the olfactory bulb.

below expectations for a primate brain of 1.5 kg, while the human cerebellum, at 154 g and 69 billion neurons, matches or even slightly exceeds the expected (**Table 2**).

Although not observed in the comparatively small rodent species analyzed, the enlargement of the cerebral cortex is not, in principle, an exclusive feature of the human brain: a similar expansion of the mass of the cerebral cortex, relative to the whole brain, is predicted by both the rodent and primate cellular scaling rules, irrespective of the number of neurons contained in the cortex (**Table 2**). Remarkably, the human cerebral cortex, which represents 82% of brain mass, holds only 19% of all neurons in the human brain – a fraction that is similar to the fraction that we observed in several other primates, rodents, and even insectivores (**Figure 1**). The relatively large human cerebral cortex, therefore, is not different from the cerebral cortex of other animals in its relative number of neurons.

It should be noted that the unchanging proportional number of neurons in the cerebral cortex relative to the whole brain does not contradict an expansion in volume, function and number of neurons of the cerebral cortex in evolution: the absolute number of neurons in the rodent and primate cerebral cortex does increase much faster in larger brains compared to the number of neurons in the combined brainstem, diencephalon and basal ganglia, and is accompanied by a similarly fast increase in the number of neurons in the cerebellum (**Figure 5**).

Because of the diverging power laws that relate brain size and number of neurons across rodents and primates, the latter can hold more neurons in the same brain volume, with larger neuronal densities than found in rodents. Since neuronal density does not scale with brain size in primates, but decreases with increasing brain size in rodents, the larger the brain size, the larger is the difference in number of neurons across similar-sized rodent and primate brains.

PREDICTIONS FOR GREAT APES

The finding that the same cellular scaling rules apply to humans and non-anthropoid primate brains alike, irrespective of body size, indicates that the brains of the great apes, which diverged from the hominin lineage before humans, should also conform to the same cellular scaling rules. An examination of the cellular composition of the cerebellum of orangutans and one gorilla shows that the sizes of the cerebellum and cerebral cortex predicted for these species from the number of cells in the cerebellum match their actual sizes, which suggests that the brain of these animals indeed is built according to the same scaling rules that apply to humans and other primates (Herculano-Houzel and Kaas, in preparation). In view of the discrepant relationship between body and brain size in humans, great apes, and non-anthropoid primates, these findings suggest that the rules that apply to scaling primate brains are much more conserved than those that apply to scaling the body. This raises the possibility that brain mass and body mass across species are only correlated, rather than brain mass being determined by body mass, as presumed in studies that focus on the variation of residuals after regression onto body size. Supportive evidence comes from the dissociation between brain and body growth in development, in which the former actually precedes the latter (reviewed in Deacon, 1997), and from our observation that body mass seems more free to vary across species than brain mass as a function of its number of neurons. In this view, it will be interesting to consider the alternative hypothesis that body size is not a determining variable for brain size in comparative studies of brain neuroanatomy, and particularly not an (independent) parameter for assessing quantitative aspects of the human brain.

DO WE HAVE THE MOST NEURONS? PREDICTIONS FOR OTHER LARGE-BRAINED MAMMALS

The different cellular scaling rules that apply to rodents and primates strongly indicate that it is not valid to use brain size as a proxy for number of neurons across humans, whales, elephants and other large-brained species belonging to different mammalian orders. One consequence of this realization is that sheer size alone, or in relation to body size, is not an adequate parameter to qualify, or disqualify, the human brain as "special".

A comparison of expected numbers can nevertheless be very illuminating. For instance, given the cellular scaling rules that we have observed for rodents (Herculano-Houzel et al., 2006), a hypothetical

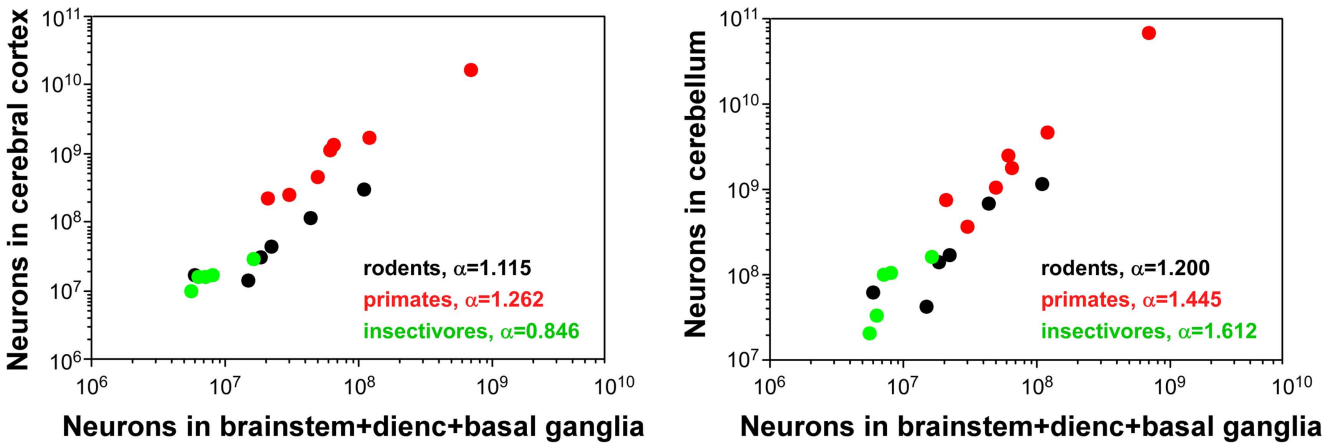

FIGURE 5 | Numbers of neurons increase faster in the cerebral cortex and cerebellum than in the remaining brain areas (the combined brainstem, diencephalon and basal ganglia). Data points indicate average values for individual species of rodents (Herculano-Houzel et al., 2006), primates (Herculano-Houzel et al., 2007), including humans (Azevedo et al., 2009), and insectivores (Sarko et al., 2009).

rodent brain with 86 billion neurons, like the human brain, would be predicted to weigh overwhelming 35 kg – a value that is way beyond the largest known brain mass of 9 kg for the blue whale, and probably physiologically unattainable. As mentioned above, a generic rodent brain of human-sized proportions, weighing 1.5 kg, would have only 12 billion neurons: in this sense, therefore, being a primate endows us with seven times more neurons than would be expected if we were rodents. Notice that this remarkable difference does not rely on assumptions about how brain size or cellular composition relate to body size in the species.

A burning question is now whether cetaceans and elephants, endowed with much larger brains than humans, also have much larger numbers of neurons than humans. According to one estimate, the false killer whale and the African elephant would have about 11 billion neurons in the cerebral cortex, despite their large size – and fewer neurons than the 11.5 billion estimated by the same method for the human cerebral cortex, though only marginally so (Roth and Dicke, 2005). These estimates, however, were obtained by simply multiplying cerebral cortical volume and the neuronal densities determined for a few cortical areas, which probably do not reflect average neuronal density in the entire cortex.

Although direct measurements of cellular composition are not yet available from whole elephant and whale brains, it is illuminating to consider how their cellular compositions would differ depending on whether predicted from the scaling rules that apply to rodent or to primate brains. As shown in **Table 3**, the difference in numbers of neurons predicted to compose the brains of the false killer whale and of the African elephant is 10-fold depending on the scaling rules employed. Speculatively, the estimate of neuronal density in the gray matter of the cerebral cortex of the whale and the elephant at a low figure of about 7000 neurons/mm^3 (Tower, 1954) suggests that these brains conform to scaling rules that are much closer to those that apply to rodents than to the primate scaling rules. It may turn out, therefore, these very large brains are composed of remarkably fewer neurons than the human brain, despite their size, thanks to the distinct, economical scaling rules that apply to primates in general (and not to humans in particular).

THE HUMAN BRAIN IS A LINEARLY SCALED-UP PRIMATE BRAIN IN ITS NUMBER OF NEURONS. WHAT NOW?

COGNITIVE ABILITIES, BRAIN SIZE AND NUMBER OF NEURONS

To conclude that the human brain is a linearly scaled-up primate brain, with just the expected number of neurons for a primate brain of its size, is not to state that it is unremarkable in its capabilities. However, as studies on the cognitive abilities of non-human primates and other large-brained animals progress, it becomes increasingly likely that humans do not have truly unique cognitive abilities, and hence must differ from these animals not qualitatively, but rather in the combination and extent of abilities such as theory of mind, imitation and social cognition (Marino et al., 2009). Quantitative changes in the neuronal composition of the brain could therefore be a main driving force that, through the exponential combination of processing units, and therefore of computational abilities, leads to events that may look like "jumps" in the evolution of brains and intelligence (Roth and Dicke, 2005). Such quantitative changes are likely to be warranted by increases in the absolute (rather than relative) numbers of neurons in relevant cortical areas and, coordinately, in the cerebellar circuits that interact with them (Ramnani, 2006). Moreover, viewing the human brain as a linearly scaled-up primate brain in its cellular composition does not diminish the role that particular neuroanatomical arrangements, such as changes in the relative size of functional cortical areas (for instance, Semendeferi et al., 2001; Rilling and Seligman, 2002), in the volume of prefrontal white matter (Schoenemann et al., 2005) or in the size of specific portions of the cerebellum (Ramnani, 2006) may play in human cognition. Rather, such arrangements should contribute to brain function in combination with the large number of neurons in the human brain. Our analysis of numbers of neurons has so far been restricted to large brain divisions, such as the entire cerebral cortex and the ensemble of brainstem, diencephalon and basal ganglia, but an analysis of the cellular scaling of separate functional cortical areas and the related subcortical structures is underway. Such data should allow us to address important issues such as mosaic evolution through concerted changes in the functionally related

Table 3 | Predicted cellular composition of whale and elephant brains if they scaled according to rodent or primate cellular scaling rules.

	Predicted from rodent rules	Predicted from primate rules
FALSE KILLER WHALE, 3650 G		
Neurons, whole brain	21 billion	212 billion
Mass, cerebral cortex	3000 g	3655 g
Neurons, cerebral cortex	3 billion	55 billion
Neuronal density, cortex	1000 neurons/mg*	30–80,000 neurons/mg**
Mass, cerebellum	304 g	279 g
Neurons, cerebellum	19 billion	140 billion
Neuronal density, cerebellum	63,500 neurons/mg*	400–600,000 neurons/mg*
AFRICAN ELEPHANT, 4200 G		
Neurons, whole brain	23 billion	241 billion
Mass, cerebral cortex	3488 g	4245 g
Neurons, cerebral cortex	3 billion	62 billion
Neuronal density, cortex	960 neurons/mg*	30–80,000 neurons/mg***
Mass, cerebellum	347 g	318 g
Neurons, cerebellum	21 billion	159 billion
Neuronal density, cerebellum	61,200 neurons/mg*	400–600,000 neurons/mg*

Neuronal densities (*) predicted from the rodent scaling rules apply to the whole structures, including white matter. Neuronal densities predicted from the primate scaling rules are the range observed in primate gray matter (**) (Herculano-Houzel et al., 2008), and in the primate cerebellum including white matter (***), since neuronal density does not covary with structure size in primates (Herculano-Houzel et al., 2007). Notice the difference in predicted numbers of neurons depending on the scaling rules applied. Given the low neuronal densities observed in the whale and elephant gray matter, of about 7000 neurons/mm^3 of gray matter, it is reasonable to speculate that the scaling rules that apply to whale and elephant brains are closer to the rules that apply to rodent brains than to the rules that apply to primate brains. Notice also that the actual size of the elephant cerebellum, at about 1 kg (Hakeem et al., 2005), is much larger than the predicted here.

components of distributed systems, and the presumed increase in relative number of neurons in systems that increase in importance (Barton and Harvey, 2000; Barton, 2006).

If cognitive abilities among non-human primates scale with absolute brain size (Deaner et al., 2007) and brain size scales linearly across primates with its number of neurons (Herculano-Houzel et al., 2007), it is tempting to infer that the cognitive abilities of a primate, and of other mammals for that matter, are directly related to the number of neurons in its brain. In this sense, it is interesting to realize that, if the same linear scaling rules are considered to apply to great apes as to other primates, then similar three-fold differences in brain size and in brain neurons alike apply to humans compared to gorillas, and to gorillas compared to baboons. This, however, is not to say that any cognitive advantages that the human brain may have over the gorilla and that the gorilla may have over the baboon are equally three-fold – although these differences are difficult to quantify. Since neurons interact combinatorially through the synapses they establish with one another, and further so as they interact in networks, the increase in cognitive abilities afforded by increasing the number of neurons in the brain can be expected to increase exponentially with absolute number of neurons, and might even be subject to a thresholding effect once critical points of information processing are reached. In this way, the effects of a three-fold increase in numbers of neurons may be much more remarkable when comparing already large brains, such as those of humans and gorillas, than when comparing small brains, such as those of squirrel monkeys and galagos.

INTRASPECIFIC VARIABILITY IN SIZE, NUMBERS AND ABILITIES

One final caveat to keep in mind when studying scaling of numbers of brain neurons, particularly in regard to cognition, is that relationships observed across species need not apply to comparisons across individuals of the same species. Not only the extent of intraspecific variation is much smaller (on the order of 10–50%) than interspecific variation (which spans five orders of magnitude within mammals; Tower, 1954; Stolzenburg et al., 1989), but also the mechanisms underlying interspecific and intraspecific variation are also likely to differ. Our own preliminary data suggest that, indeed, variations in brain size across rats of the same age are not correlated with variations in numbers of neurons (Morterá and Herculano-Houzel, unpublished observations). There is no justification, therefore, to extend the linear correlation between brain size and number of neurons across primates to a putative correlation across persons of different brain sizes (which might be used, inappropriately, as grounds for claims that larger-brained individuals have more neurons, and are therefore "smarter", than smaller-brained persons). In fact, although men have been reported to have more neurons in the cerebral cortex than women (Pakkenberg and Gundersen, 1997; Pelvig et al., 2008), there is no significant correlation between brain size and general cognitive ability within families (Schoenemann et al., 2000). Across these individuals, other factors such as variations in number and identity of synaptic connections within and across structures, building on a statistically normal, albeit variable, number of neurons, and depending on genetics and life experiences such as learning, are more likely to be determinant of the individual cognitive abilities (see, for instance, Mollgaard et al., 1971; Black et al., 1990; Irwin et al., 2000; Draganski et al., 2004).

CONCLUDING REMARKS: OUR PLACE IN NATURE

Novel quantitative data on the cellular composition of the human brain and its comparison to other primate brains strongly indicate that we need to rethink our notions about the place that the human brain holds in nature and evolution, and rewrite some of the basic concepts

that are taught in textbooks. Accumulating evidence (Deacon, 1997; Roth and Dicke, 2005; Deaner et al., 2007) indicates that an alternative view of the source of variations in cognitive abilities across species merits investigation: one that disregards body and brain size and examines absolute numbers of neurons as a more relevant parameter instead. Now that these numbers can be determined in various brains and their structures, direct comparisons can be made across species and orders, with no assumptions about body–brain size relationships required. Complementarily, however, it now becomes possible to examine how numbers of neurons in the brain, rather than brain size, relate to body mass and surface as well as metabolism, parameters that have been considered relevant in comparative studies (Martin, 1981; Fox and Wilczynski, 1986; MacLarnon, 1996; Schoenemann, 2004), in order to establish what mechanisms underlie the loosely correlated scaling of body and brain.

According to this now possible neuron-centered view, rather than to the body-centered view that dominates the literature (see Gazzaniga, 2008, for a comprehensive review), the human brain has the number of neurons that is expected of a primate brain of its size; a cerebral cortex that is exactly as large as expected for a primate brain of 1.5 kg; just as many neurons as expected in the cerebral cortex for the size of this structure; and, despite having a relatively large cerebral cortex (which, however, a rodent brain of 1.5 kg would also be predicted to have), this enlarged cortex holds just the same proportion of brain neurons in humans as do other primate cortices (and rodent cortices, for that matter). This final observation calls for a reappraisal of the view of brain evolution that concentrates on the expansion of the cerebral cortex, and its replacement with a more integrated view of coordinate evolution of cellular composition, neuroanatomical structure, and function of cerebral cortex and cerebellum (Whiting and Barton, 2003).

Other "facts" that deserve updating are the ubiquitous quote of 100 billion neurons (a value that lies outside of the margin of variation found so far in human brains; Azevedo et al., 2009), and, more strikingly, the widespread remark that there are 10× more glial cells than neurons in the human brain. As we have shown, glial cells in the human brain are at most 50% of all brain cells, which is an important finding since it is one more brain characteristic that we share with other primates (Azevedo et al., 2009).

Finally, if being considered the bearer of a linearly scaled-up primate brain does not sound worthy enough for the animal that considers himself the most cognitively able on Earth, one can note that there are, indeed, two advantages to the human brain when compared to others – even if it is not an outlier, nor unique in any remarkable way. First, the human brain scales as a primate brain: this economical property of scaling alone, compared to rodents, assures that the human brain has many more neurons than would fit into a rodent brain of similar size, and possibly into any other similar-sized brain. And second, our standing among primates as the proud owners of the largest living brain assures that, at least among primates, we enjoy the largest number of neurons from which to derive cognition and behavior as a whole. It will now be interesting to determine whether humans, indeed, have the largest number of neurons in the brain among mammals as a whole.

ACKNOWLEDGMENTS

Thanks to Roberto Lent and Jon Kaas for continued support and encouragement, to Bruno Mota for insightful discussions, and to the colleagues who participated in the quantification of the cellular composition of the brain of various species. The role of inflammation in depression: from evolutionary imperative to modern treatment target

Andrew H. Miller[1] and Charles L. Raison[2]

Abstract | Crosstalk between inflammatory pathways and neurocircuits in the brain can lead to behavioural responses, such as avoidance and alarm, that are likely to have provided early humans with an evolutionary advantage in their interactions with pathogens and predators. However, in modern times, such interactions between inflammation and the brain appear to drive the development of depression and may contribute to non-responsiveness to current antidepressant therapies. Recent data have elucidated the mechanisms by which the innate and adaptive immune systems interact with neurotransmitters and neurocircuits to influence the risk for depression. Here, we detail our current understanding of these pathways and discuss the therapeutic potential of targeting the immune system to treat depression.

Conspecifics
Members of the same species.

Depression is a devastating disorder, afflicting up to 10% of the adult population in the United States and representing one of the leading causes of disability worldwide[1]. Although effective treatments are available, approximately one third of all patients with depression fail to respond to conventional antidepressant therapies[2], further contributing to the global burden of the disease. Accordingly, there is a pressing need for new conceptual frameworks for understanding the development of depression to develop better treatments. In this Review, we outline emerging data that point to the immune system — and, in particular, the inflammatory response — as a potentially important contributor to the pathophysiology of depression. We first consider the origins of this notion from an evolutionary perspective, examining the advantages of depressive behaviours in the context of host immune responses to pathogens, predators and conspecifics in ancestral environments. The pivotal role of psychosocial stress in the modern world are then examined, highlighting inflammasome activation and immune cell trafficking as novel mechanisms by which stress-induced inflammatory signals can be transmitted to the brain. Neurotransmitters and neurocircuits that are targets of the inflammatory response are also explored followed by an examination of brain–immune interactions as risk and resilience factors for depression. Finally, these interactions are discussed as a foundation for a new era of therapeutics that target the immune system to treat depression, with a focus on how immunological biomarkers can be used to personalize care.

An evolutionary perspective

Data from humans and laboratory animals provide compelling evidence that stress-relevant neurocircuitry and immunity form an integrated system that evolved to protect organisms from a wide range of environmental threats. For example, in the context of a laboratory stressor that entails delivering a speech to a judgmental panel of supposed 'behavioural experts', subjects experience a classic 'fight or flight' response characterized by increases in heart rate and blood pressure as well as in cortisol and catecholamines. But something else happens within the body that demands a deeper explanation. The stressor activates key inflammatory pathways in peripheral blood mononuclear cells, including activation of the transcription factor nuclear factor-κB (NF-κB), and leads to marked increases in circulating levels of pro-inflammatory cytokines, such as interleukin-6 (IL-6)[3,4]. In essence, the body mounts an immune response not against a pathogen, but against a threat to the subject's self-esteem. Moreover, individuals at high risk of developing depression (for example, those who have experienced early-life trauma) show increased inflammatory responses to such laboratory stressors compared with low-risk individuals[3]. Furthermore, the greater the inflammatory response to a psychosocial stressor, the more probable the subject is to develop depression over the ensuing months[5]. Two questions immediately present themselves: why should a stimulus devoid of any pathogen induce an inflammatory response, and why should this response promote the development of depression?

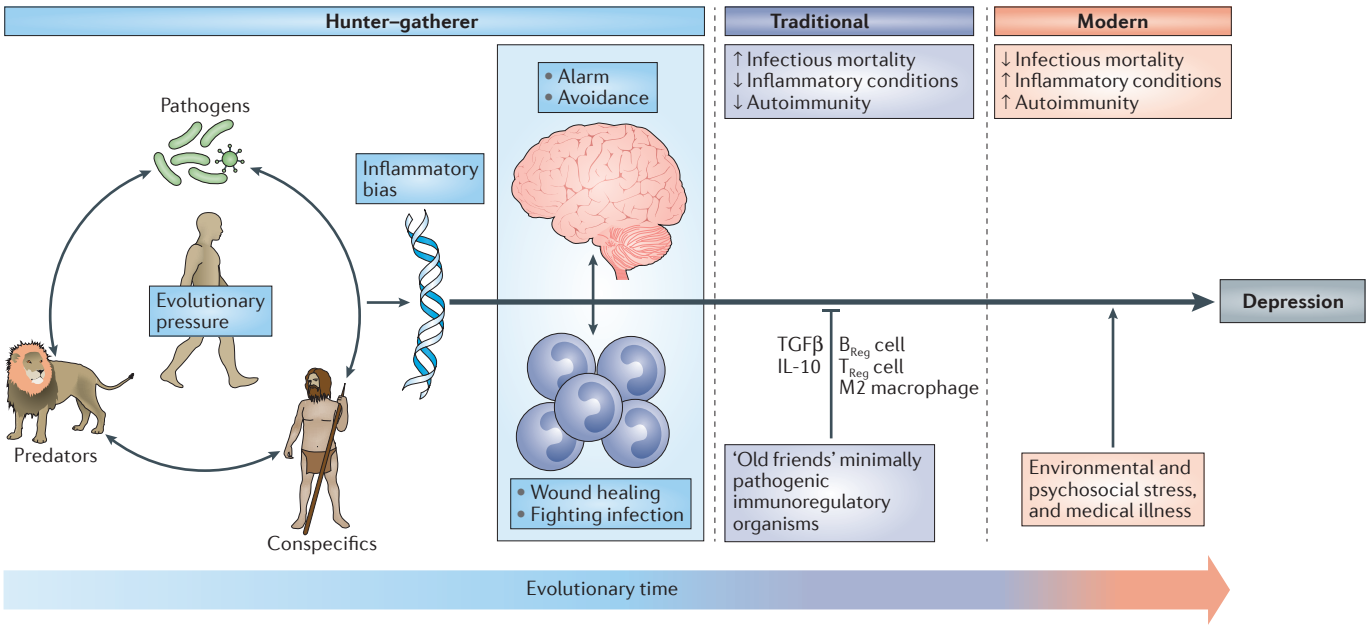

Figure 1 | **Evolutionary legacy of an inflammatory bias.** Early evolutionary pressures derived from human interactions with pathogens, predators and human conspecifics (such as rivals) resulted in an inflammatory bias that included an integrated suite of immunological and behavioural responses that conserved energy for fighting infection and healing wounds, while maintaining vigilance against attack. This inflammatory bias is believed to have been held in check during much of human evolution by exposure to minimally pathogenic, tolerogenic organisms in traditional (that is, rural) environments that engendered immunological responses characterized by the induction of regulatory T (T_{Reg}) cells, regulatory B (B_{Reg}) cells and immunoregulatory M2 macrophages as well as the production of the anti-inflammatory cytokines interleukin-10 (IL-10) and transforming growth factor-β (TGFβ). In modern times, sanitized urban environments of more developed societies are rife with psychological challenges but generally lacking in the types of infectious challenges that were primary sources of morbidity and mortality across most of human evolution. In the absence of traditional immunological checks and balances, the psychological challenges of the modern world instigate ancestral immunological and behavioural repertoires that represent a decided liability, such as high rates of various inflammation-related disorders including depression.

Pathogen host defence and depression. No coherent answer to these questions is apparent if immunity is viewed as merely another physiological system within the body. However, when seen against the back-drop of millions of years of co-evolution between mammals and the world of microorganisms and parasites, the human inflammatory bias exposed by laboratory stressors and reflected in the association between immune activation and depression not only makes imminent adaptive sense but also provides insight into a paradox deep within the heart of depression itself; namely, why are the genetic alleles that are most frequently associated with depression so common in the modern gene pool[6] (FIG. 1)?

Most adaptive theories of depression have focused on the potential benefits of depressive symptoms for relationships with other humans[7]. However, recent models have shifted the focus away from relationships with people, to relationships — both detrimental and beneficial — with pathogens[6,8]. These theories, which are supported by converging evidence (BOX 1), posit that modern humans have inherited a genomic bias towards inflammation because this response — and the depressive symptoms it promotes — enhanced host survival and reproduction in the highly pathogenic environments in which humans evolved[6]. From this theoretical perspective, at least some of the human vulnerability to depression evolved out of a behavioural repertoire — often referred to as 'sickness behaviour' — which promoted host survival in the face of infection. Indeed, it has been hypothesized that the social avoidance and anhedonia characteristic of depression serve to shunt energy resources to fighting infection and wound healing, whereas the hypervigilance characteristic of anxiety disorders, commonly co-morbid with depression, subserves protection from attack and subsequent pathogen exposure[6,9]. Even psychological stress can be understood from this theoretical perspective, given that the vast majority of stressors faced by mammals over evolutionary time boiled down to risks inherent in hunting, being hunted or competing for reproductive access or status. In all of these circumstances, the risk of pathogen invasion — and subsequent death from infection — was greatly increased as a result of wounding. In ancestral environments, the association between stress perception and risk of subsequent wounding was reliable enough that evolution favoured organisms that prepotently activated inflammatory systems in response to a wide array of environmental threats and challenges (including psychosocial stressors), even if this activation was often a 'false alarm' (REF. 6).

Sickness behaviour
An adaptive response to illness, often precipitated by infection, that includes social withdrawal, decreased appetite, lethargy, impaired concentration, depressed mood, irritability, muscle aches and pain, and fever. This syndrome is believed to prioritize shifting of energy resources to fighting infection and wound healing.

Anhedonia
A lack of interest in usually pleasurable activities that represents a decrease in motivation, which can either represent a decrease in the response to reward or in the willingness to expend effort to obtain reward.

Box 1 | **Pathogen host defence hypothesis of depression**

Several lines of evidence support the notion that the evolution and persistence of depression risk alleles and depressive symptoms in human populations are based on their relevance to 'pathogen host defence'. This evidence includes:

- Until recently, approximately 50% of humans died from infectious causes before adulthood, thereby providing strong selective pressure for genetic alleles that enhance host defence[124].
- As a result of strong selective pressure, microbial interactions have been a primary driver of human evolution[125].
- Patterns of inflammatory activation associated with depression promote survival in highly pathogenic environments while increasing mortality in sanitary conditions common in the developed world[126].
- The best replicated risk alleles for depression have pro-inflammatory and/or anti-pathogen protective effects or have been implicated in social behaviours that are likely to reduce pathogen exposure[6].
- Environmental risk factors for the development of depression (that is, psychosocial stress, early life adversity, obesity and processed-food diet) are uniformly pro-inflammatory[13].
- Exposure to pro-inflammatory cytokines produces a sickness syndrome with symptoms that overlap considerably with those seen in depression and that can be ameliorated by treatment with antidepressants[23]. In addition, the onset of depression is often mistaken with development of sickness, and symptoms associated with infections are often mistaken with the onset of depression[127].
- Chronic cytokine exposure produces a combination of withdrawal and/or energy conservation, anxiety and/or hypervigilance behaviours and emotions that commonly coexist in depression[6,9].
- Symptoms shared by depression and sickness behaviour — such as hyperthermia and reduced iron availability — that lack any conceivable social value have potent anti-pathogen effects[6].

The 'pathogen host defence' hypothesis of depression may also provide insight into the twofold increase in depression in women compared to men, especially during the reproductive years[10]. Recent data indicate that women are more sensitive to the behavioural effects of inflammation, demonstrating greater increases in depressed mood than men following endotoxin exposure despite a similar magnitude in cytokine (IL-6 and tumour necrosis factor (TNF)) responses[11]. Women also exhibit a greater likelihood than men to develop depression in response to standardized doses of interferon-α (IFNα)[12]. By being more sensitive to inflammation-induced depressive symptoms, women may have benefited more from the protection provided by these symptoms in terms of fighting infection, healing wounds and avoiding subsequent pathogen exposure. Given the potentially negative impact of inflammation on reproductive success (for example, by reducing fertility and impairing lactation), the increase of depressive symptoms in women across evolutionary time may have given women of reproductive age an advantage in coping with and avoiding pathogens and the related inflammation, with increased depressive disorders being the ultimate trade-off in modern times.

Modern exaggeration of the inflammatory bias. The prevalence of autoimmune, allergic and inflammatory diseases has markedly increased in the past 100 years, and rates of these conditions follow a similar upward trajectory in societies transitioning from traditional (that is, rural) to modern (that is, urban) ways of life[13]. Increasing evidence suggests that this pattern of widespread immune dysregulation may result from disruptions in our relationship and/or contact with a variety of co-evolved, non-lethal immunoregulatory microorganisms and parasites, especially commensals and symbiotes in the microbiotas of the gut, skin and nasal and oral cavities, that were ubiquitous in the natural environments in which humans evolved[14]. Although widely disparate, these organisms (often referred to as 'old friends') share a tendency to reduce inflammation and suppress effector immune cells through the induction of IL-10 and transforming growth factor-β (TGFβ) while promoting the development of anti-inflammatory immune cell populations, such as alternatively activated (also referred to as 'M2') macrophages and regulatory T (T_{Reg}) cells and regulatory B cells[13,14] (FIG. 1). Owing to various cultural changes, including the loss of exposure to microbial diversity with the advent of sanitation practices, modern humans now lack this immunoregulatory input — especially during infancy and childhood. Consequently, we find ourselves in a condition of an exacerbated inflammatory bias, with the particular conditions afflicting any given individual largely the result of genetic predisposition and environmental (for example, psychosocial) exposures[13,14], ultimately accounting for the high co-morbidity between depression and autoimmune, allergic and inflammatory disorders[13,15].

Inflammation and depression

Data supporting the role of inflammation in depression are extensive and include findings that span experimental paradigms. Patients with major depressive disorder exhibit all of the cardinal features of an inflammatory response, including increased expression of pro-inflammatory cytokines and their receptors and increased levels of acute-phase reactants, chemokines and soluble adhesion molecules in peripheral blood and cerebrospinal fluid (CSF)[16,17]. Peripheral blood gene expression profiles consistent with a pro-inflammatory 'M1' macrophage phenotype and an over-representation of IL-6, IL-8 and type I IFN-induced signalling pathways have also been described[18–20]. In addition, increased expression of a variety of innate immune genes and proteins, including IL-1β, IL-6, TNF, Toll-like receptor 3 (TLR3) and TLR4, has been found in post-mortem brain samples from suicide victims that had depression[16,18,19,21]. Meta-analyses of the literature conclude that peripheral blood IL-1β, IL-6, TNF and C-reactive protein (CRP) are the most reliable biomarkers of inflammation in patients with depression[16]. Polymorphisms in inflammatory cytokine genes, including those encoding IL-1β, TNF and CRP, have also been associated with depression and its response to treatment[22]. Moreover, other genes implicated in depression derived from meta-analyses of genome-wide association studies have been linked to the immune response and the response to pathogens including TNF[6] (BOX 1). Administration of inflammatory cytokines (for example, IFNα) or their inducers (for example, endotoxin or typhoid vaccination) to otherwise non-depressed individuals causes

symptoms of depression[23–26]. Furthermore, blockade of cytokines, such as TNF, or of inflammatory signalling pathway components, such as cyclooxygenase 2, has been shown to reduce depressive symptoms in patients with medical illnesses, including rheumatoid arthritis, psoriasis and cancer, as well as in patients with major depressive disorder[27–29].

As the field has matured, it has become increasingly apparent that inflammatory markers are elevated not only in a subgroup of patients with depression[30,31] but also in patients with other neuropsychiatric disorders including anxiety disorders and schizophrenia[32,33]. Moreover, as described below, it may be more accurate to characterize the impact of inflammation on behaviour as being associated not wholly with depression but with specific symptom dimensions across diagnoses that align with the Research Domain Criteria framework put forth by the National Institute of Mental Health (US Department of Health and Human Services). These symptoms, including positive and negative valence systems, relate to altered motivation and motor activity (anhedonia, fatigue and psychomotor impairment) and increased threat sensitivity (anxiety, arousal and alarm)[34]. Finally, inflammation has been associated with antidepressant treatment non-responsiveness[9,32,35–37]. For example, in a recent study, 45% of patients with non-response to conventional antidepressants exhibited a CRP >3 mg L^{-1} (REF. 30), which is considered indicative of a high level of inflammation on the basis of widely accepted cut-off points[38]. Of note, however, the percentage of patients with high CRP levels can vary as a function of the population being studied, with higher percentages in patients with depression and treatment resistance, childhood maltreatment, medical illnesses and metabolic syndrome.

Immune pathways involved in depression

Inflammasomes: stress in translation. Exposure to psychosocial stress is one of the most robust and reproducible predictors of developing depression in humans and is the primary experimental pathway to depressive-like behaviour in laboratory animals. Thus, the observation that exposure to a psychosocial laboratory stressor can activate an inflammatory response in humans was a major breakthrough in linking inflammation to depression[3,4]. An important question for the field, however, is by what mechanism is stress translated into inflammation? Although considerable attention has been paid to stress-induced neuroendocrine pathways, including the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic nervous system (SNS), both of which have immunomodulatory functions[39], recent focus has been shifted towards inflammasomes, which may represent a crucial immunological interface between stress and inflammation[40] (FIG. 2). Inflammasomes are cytosolic protein complexes that form in myeloid cells in response to pathogenic microorganisms and non-pathogenic or 'sterile' stressors. Assembly of the inflammasome leads to activation of caspase 1, which then cleaves the precursor forms of IL-1β and IL-18 into the active cytokines[41]. Given the relatively sterile nature of psychosocial stress, primary interest has been directed towards understanding how inflammasome activation in depression may be triggered by endogenous damage-associated molecular patterns (DAMPs), including ATP, heat shock proteins (HSPs), uric acid, high mobility group box 1 (HMGB1) and a variety of molecules linked with oxidative stress. Indeed, all of these DAMPs are induced by the psychological and mixed (that is, psychological and physiological) stressors used in animal models of depression[42]; an effect that is in part mediated by stress-induced release of catecholamines[43]. Moreover, studies in laboratory animals indicate that chronic mild-stress activates the NOD-, LRR- and pyrin domain-containing protein 3 (NLRP3) inflammasome, which is well-known to respond to DAMPs[44,45]. Blockade of NLRP3 reverses stress-induced increases in IL-1β in the peripheral blood and brain, while also abrogating depressive-like behaviour in mice[45]. Interestingly, NLRP3 inflammasome upregulation and caspase-mediated cleavage of the glucocorticoid receptor can cause resistance to the effects of glucocorticoids, which are among the most potent anti-inflammatory hormones in the body[46,47]. Stress-induced glucocorticoid resistance is a well-characterized biological abnormality in patients with major depressive disorder and has been associated with increased inflammation[48,49].

Supporting the potential role of the NLRP3 inflammasome in human depression are data demonstrating that increased expression of NLRP3 and caspase 1 in peripheral blood mononuclear cells of patients with depression is associated with increased blood concentrations of IL-1β and IL-18, which in turn correlate with depression severity[19,50]. In addition, DAMPs that are known to activate NLRP3 are increased in patients with mood disorders, with examples including HSPs, reactive oxygen species and other markers of oxidative stress such as xanthine oxidase, peroxides and F2-isoprostanes[51–53]. Finally, there is increasing interest in the potential role of the gut microbiome in mood regulation, which may be mediated in part by the inflammasomes[54]. Indeed, non-pathogenic commensal bacteria and derived microbial-associated molecular patterns (MAMPs) in the gut can leak into the peripheral circulation during stress and activate the inflammasomes[55], a process mediated by the SNS and catecholamines[56] (FIG. 2). Of note, stress-induced increases in IL-1β and IL-18 were attenuated by treating animals with antibiotics or neutralizing lipopolysaccharide (LPS), demonstrating the importance of the composition of the gut microbiome and gut permeability in stress-induced inflammatory responses[55]. Taken together, these data support the notion that the inflammasome may be a key immunological point of integration of stress-induced danger signals that ultimately drive inflammatory responses relevant to depression.

Transmitting inflammatory signals to the brain. In addition to increased expression of innate immune cytokines and TLRs in post-mortem brain samples from suicide victims with depression, evidence of microglial and astroglial activation in several brain regions including frontal cortex, anterior cingulate cortex (ACC)

© 2015 Macmillan Publishers Limited. All rights reserved

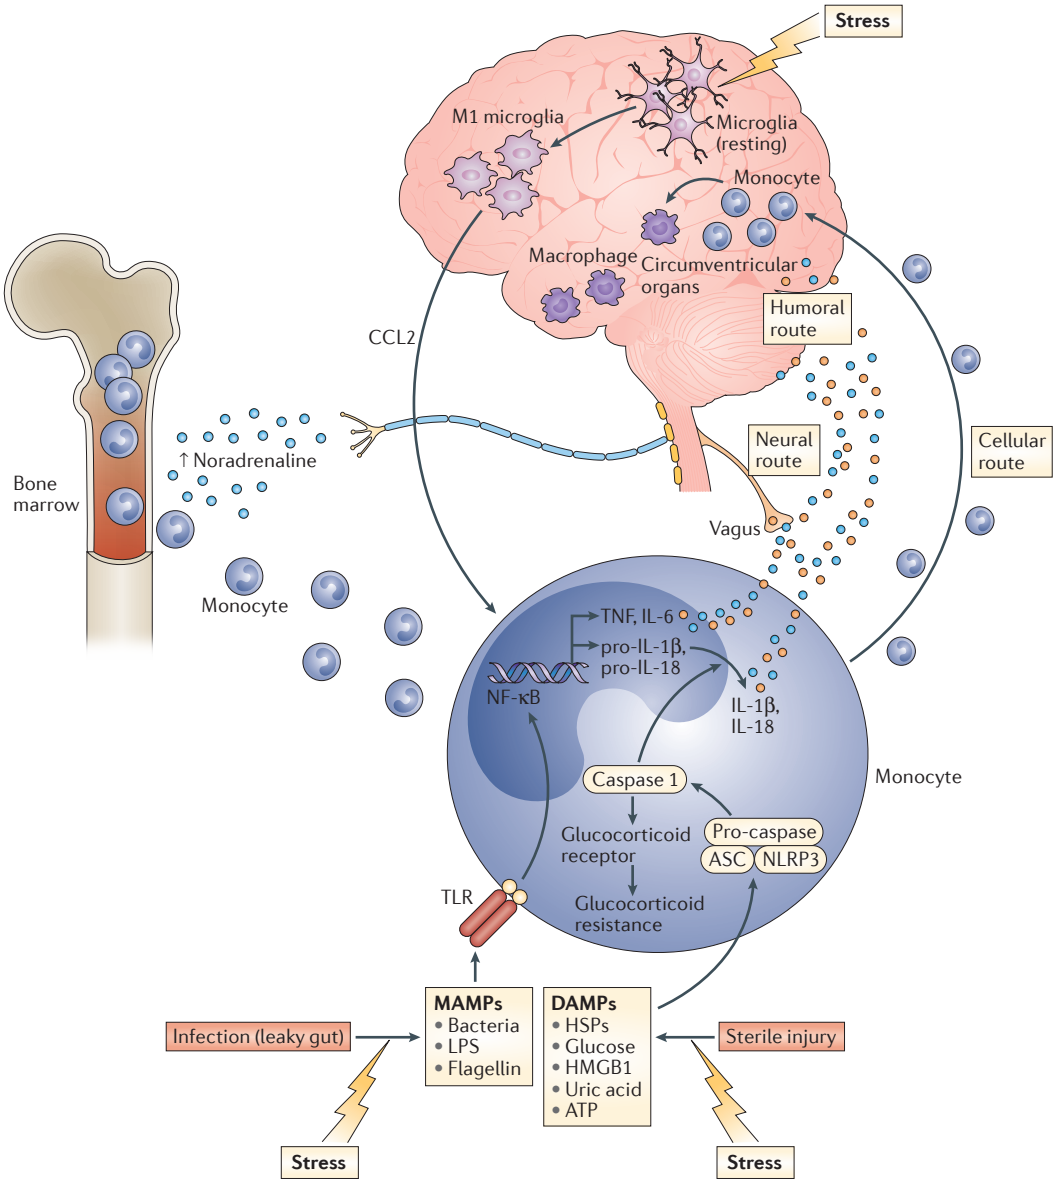

Figure 2 | **Transmitting stress-induced inflammatory signals to the brain.** In the context of psychosocial stress, catecholamines (such as noradrenaline) released by activated sympathetic nervous system fibres stimulate bone marrow production and the release of myeloid cells (for example, monocytes) that enter the periphery where they encounter stress-induced damage-associated molecular patterns (DAMPs), bacteria and bacterial products such as microbial-associated molecular patterns (MAMPs) leaked from the gut. These DAMPs and MAMPs subsequently activate inflammatory signalling pathways such as nuclear factor-κB (NF-κB) and the NOD-, LRR- and pyrin domain-containing protein 3 (NLRP3) inflammasome. Stimulation of NLRP3 in turn activates caspase 1, which leads to the production of mature interleukin-1β (IL-1β) and IL-18 while also cleaving the glucocorticoid receptor contributing to glucocorticoid resistance. Activation of NF-κB stimulates the release of other pro-inflammatory cytokines including tumour necrosis factor (TNF) and IL-6, which together with IL-1β and IL-18 can access the brain through humoral and neural routes. Psychosocial stress can also lead to the activation of microglia to a M1 pro-inflammatory phenotype, which release CC-chemokine ligand 2 (CCL2) that in turn attracts activated myeloid cells to the brain via a cellular route. Once in the brain, activated macrophages can perpetuate central inflammatory responses. ASC, apoptosis-associated speck-like protein containing a CARD; HMGB1, high mobility group box 1; HSP, heat shock protein; LPS, lipopolysaccharide; TLR, Toll-like receptor.

and thalamus in post-mortem studies of patients with depression have been described[57–59,60]. Moreover, a well-controlled neuroimaging study using positron emission tomography (PET) and a radiolabelled tracer for the translocator protein (TSPO) — which is overexpressed in activated microglia, macrophages and astrocytes — revealed increased immune activation in the brains of patients with major depressive disorder compared with control subjects[61]. Of note, not all studies have revealed increased TSPO binding in patients with depression, possibly owing to effects of medication and/or a paucity of subjects with increased inflammation[61,62]. However,

© 2015 Macmillan Publishers Limited. All rights reserved

data from endotoxin administration to healthy volunteers indicates that radiolabelled TSPO ligands can readily identify cellular activation in several regions of the brain following a potent peripheral immune stimulus[63].

Work from laboratory animal studies has elucidated several pathways through which inflammatory signals can be transmitted from the periphery to the brain (FIG. 2). These data support the idea that inflammatory responses in peripheral tissues may drive inflammation in the brain leading to depression. Much of the early work focused on how inflammatory cytokines, which are relatively large molecules, could cross the blood–brain barrier (BBB) and influence brain function[64]. Two major pathways have been described: the 'humoral pathway', which involves cytokine passage through leaky regions in the BBB, such as the circumventricular organs, and the binding of cytokines to saturable transport molecules on the BBB; and the 'neural pathway', which involves the binding of cytokines to peripheral afferent nerve fibres, such as the vagus nerve, that in turn stimulate ascending catecholaminergic fibres in the brain and/or are translated back into central cytokine signals[16]. More recently, however, attention has shifted to a third pathway referred to as the 'cellular pathway', which involves the trafficking of activated immune cells, typically monocytes, to the brain vasculature and parenchyma. The details of this pathway have been elegantly dissected in the context of behavioural changes in mice that are associated with peripherally induced inflammation in the liver[65]. In these studies, the release of TNF from inflamed liver was found to stimulate microglial cell production of CC-chemokine ligand 2 (CCL2; also known as MCP1) that then attracted monocytes to the brain[65]. Blockade of monocyte infiltration to the brain using antibodies specific for the adhesion molecules P-selectin and α4 integrin abrogated depressive-like behaviour in this animal model[65]. Of note, cytokine-stimulated astrocytes also may be major producers of chemokines, such as CCL2 and CXC-chemokine ligand 1 (CXCL1), that attract immune cells to the brain[66]. The cellular pathway additionally has been elucidated in the context of social defeat stress, whereby GFP-labelled monocytes coalesced in several regions of the brain associated with the detection of threat (for example, amygdala) — an effect that was dependent on CCL2 and was facilitated by mobilization of monocytes from the bone marrow as a result of stress-induced release of catecholamines[67,68] (FIG. 2). Of note, initial microglial activation during social defeat stress appeared to be a result of neuronal activation by catecholamines and decreased neuronal production of CX_3C-chemokine ligand 1 (CX_3CL1; also known as fractalkine), which maintains microglia in a quiescent state[67,68]. Interestingly, this cellular pathway has received intriguing support from post-mortem analyses of brain tissue from patients with depression who committed suicide that showed increased numbers of perivascular macrophages in association with increased gene expression of allograft inflammatory factor 1 (AIF1, also known as IBA1) and CCL2, which are associated with macrophage activation and cellular trafficking[59].

Social defeat stress
A model of depression that entails repeated exposure to a conspecific animal screened for aggressive behaviour. The animals are placed together in the same cage where they are exposed to brief bouts of defeat lasting 5–10 minutes daily typically for 6–10 days.

This evidence of peripheral myeloid cells trafficking to the brain during depression constitutes some of the first data supporting the existence of a central inflammatory response in human depression that is primarily driven by peripheral inflammatory events. Moreover, data demonstrate that antibodies that are specific for TNF but which do not cross the BBB, can block stress-induced depression in mice[69]. These findings indicate that peripheral inflammatory responses not only can provide important clues to the immunological mechanisms of inflammation in depression but also may serve as biomarkers and targets of immune-based therapies for depression. Protein biomarkers such as plasma CRP and TNF as well as immunotherapies targeting individual cytokines such as TNF, IL-1 and IL-6 may be most relevant in this regard. Of note, plasma CRP is a strong response predictor in anti-cytokine therapy[70].

Cytokines and neurotransmitters. Given the pivotal importance of neurotransmission to mood regulation, attention has been paid to the impact of inflammation and inflammatory cytokines on the monoamines serotonin, noradrenaline and dopamine, as well as on the excitatory amino acid glutamate (FIG. 3). There are several pathways through which inflammatory cytokines can lead to reduced synaptic availability of the monoamines, which is believed to be a fundamental mechanism in the pathophysiology of depression[71]. For example, IL-1β and TNF induction of p38 mitogen-activated protein kinase (MAPK) has been shown to increase the expression and function of the reuptake pumps for serotonin, leading to decreased synaptic availability of serotonin and depressive-like behaviour in laboratory animals[72]. Through the generation of reactive oxygen and nitrogen species, inflammatory cytokines have also been found to decrease the availability of tetrahydrobiopterin (BH4), a key enzyme co-factor in the synthesis of all monoamines that is highly sensitive to oxidative stress[73]. Indeed, CSF concentrations of BH4 have been shown to be negatively correlated with CSF levels of IL-6 in patients treated with the inflammatory cytokine IFNα[74]. In addition, the plasma phenylalanine to tyrosine ratio, an indirect measure of BH4 activity, was shown to correlate with CSF concentrations of dopamine as well as symptoms of depression in IFNα-treated patients[74]. Activation of the enzyme indoleamine 2,3-dioxygenase (IDO) is also believed to be involved in cytokine-induced neurotransmitter alterations, in part by diverting the metabolism of tryptophan (the primary amino acid precursor of serotonin) into kynurenine, a compound that can be converted into the neurotoxic metabolite quinolinic acid by activated microglia and infiltrating monocytes and macrophages in the brain[75,76]. Of note, increased levels of quinolinic acid have been found in microglia in the ACC of suicide victims who suffered from depression[77]. Quinolinic acid directly activates receptors for glutamate (that is, *N*-methyl-D-aspartate (NMDA) receptors) while also stimulating glutamate release and blocking glutamate reuptake by astrocytes[78]. The effects of quinolinic acid on glutamate converge with the direct effects of

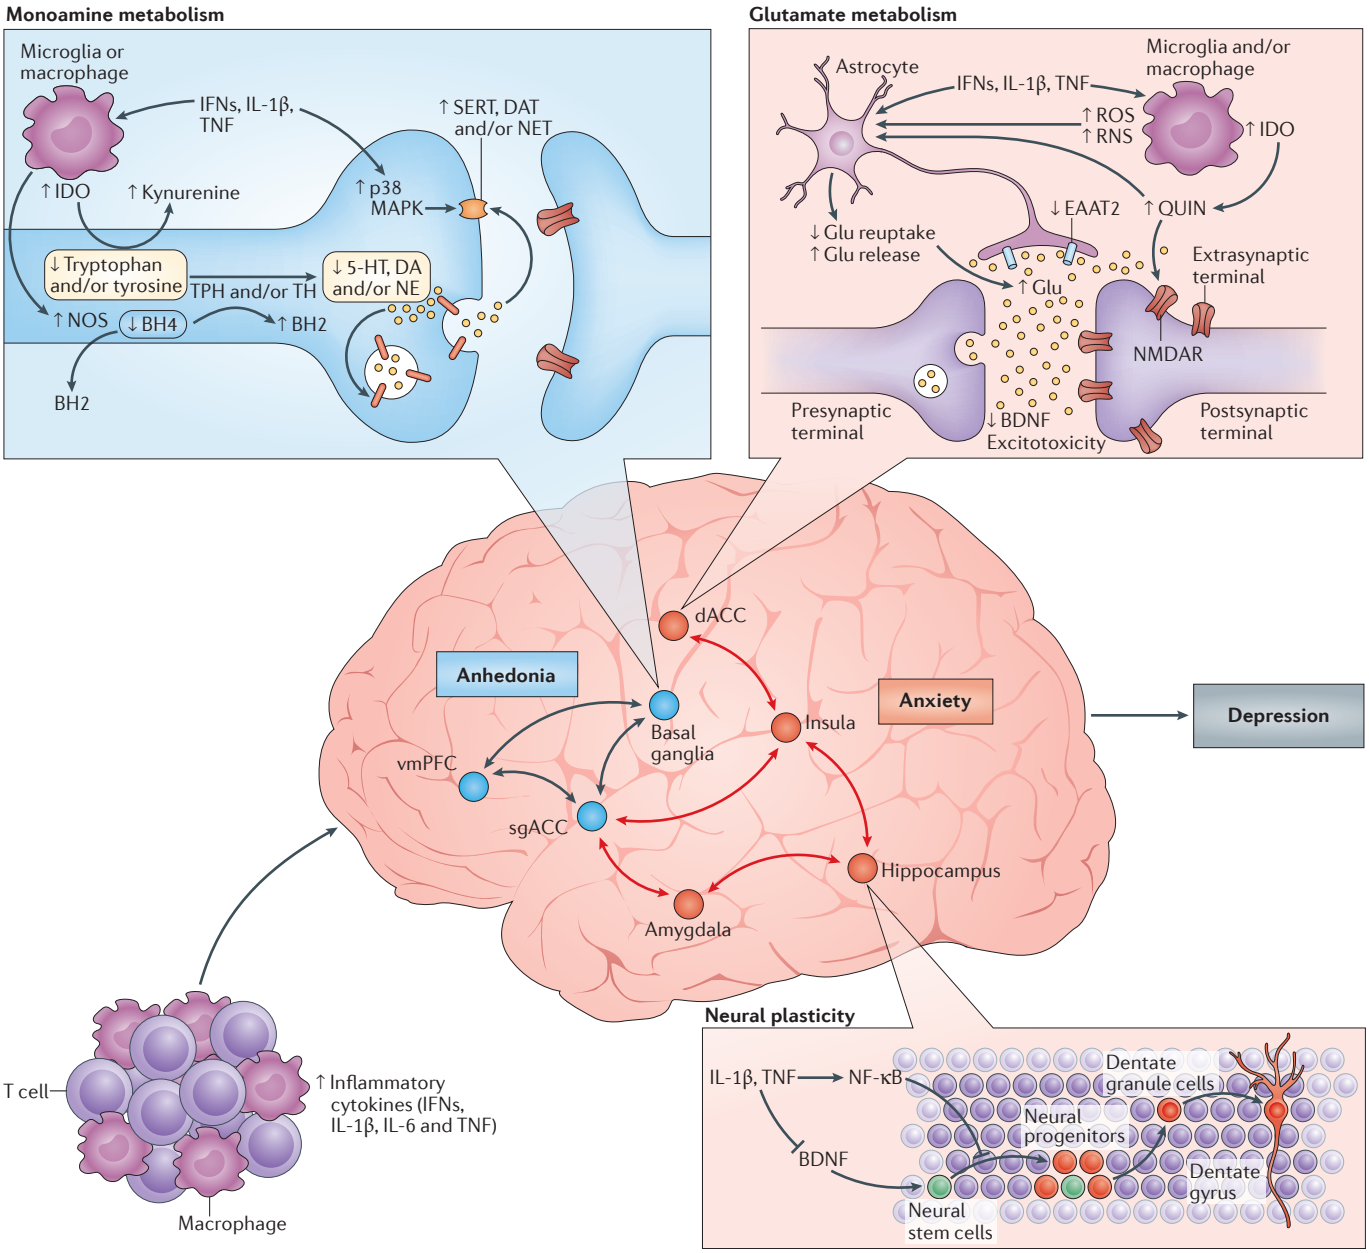

Figure 3 | **Cytokine targets in the brain: neurotransmitters and neurocircuits.** Once in the brain, the inflammatory response can affect metabolic and molecular pathways influencing neurotransmitter systems that can ultimately affect neurocircuits that regulate behaviour, especially behaviours relevant to decreased motivation (anhedonia), avoidance and alarm (anxiety), which characterize several neuropsychiatric disorders including depression. On a molecular level, pro-inflammatory cytokines including type I and II interferons (IFNs), interleukin-1β (IL-1β) and tumour necrosis factor (TNF) can reduce the availability of monoamines — serotonin (5-HT), dopamine (DA) and noradrenaline (NE) — by increasing the expression and function of the presynaptic reuptake pumps (transporters) for 5-HT, DA and NE through activation of mitogen-activated protein kinase (MAPK) pathways and by reducing monoamine synthesis through decreasing enzymatic co-factors such as tetrahydrobiopterin (BH4), which is highly sensitive to cytokine-induced oxidative stress and is involved in the production of nitric oxide (NO) by NO synthase (NOS). Many cytokines, including IFNγ, IL-1β and TNF, can also decrease relevant monoamine precursors by activating the enzyme indoleamine 2,3-dioxygenase (IDO), which breaks down tryptophan, the primary precursor for serotonin, into kynurenine. Activated microglia can convert kynurenine into quinolinic acid (QUIN), which binds to the *N*-methyl-D-aspartate receptor (NMDAR), a glutamate (Glu) receptor, and together with cytokine-induced reduction in astrocytic Glu reuptake and stimulation of astrocyte Glu release, in part by induction of reactive oxygen species (ROS) and reactive nitrogen species (RNS), can lead to excessive Glu, an excitatory amino acid neurotransmitter. Excessive Glu, especially when binding to extrasynaptic NMDARs, can in turn lead to decreased brain-derived neurotrophic factor (BDNF) and excitotoxicity. Inflammation effects on growth factors such as BDNF in the dentate gyrus of the hippocampus can also affect fundamental aspects of neuronal integrity including neurogenesis, long-term potentiation and dendritic sprouting, ultimately affecting learning and memory. Cytokine effects on neurotransmitter systems, especially DA, can inhibit several aspects of reward motivation and anhedonia in corticostriatal circuits involving the basal ganglia, ventromedial prefrontal cortex (vmPFC) and subgenual and dorsal anterior cingulate cortex (sgACC and dACC, respectively), while also activating circuits regulating anxiety, arousal, alarm and fear including the amygdala, hippocampus, dACC and insula. BH2, dihydrobiopterin; DAT, dopamine transporter; EAAT2, excitatory amino acid transporter 2; NET, noradrenaline transporter; NF-κB, nuclear factor-κB; SERT, serotonin transporter; TH, tyrosine hydroxylase; TPH, tryptophan hydroxylase. pro-inflammatory cytokines on glutamate metabolism that include decreasing the expression of astrocyte glutamate reuptake pumps and stimulating astrocytic glutamate release[79], ultimately contributing to excessive glutamate both within and outside the synapse. The binding of glutamate to extrasynaptic NMDA receptors leads to increased excitotoxicity and decreased production of brain-derived neurotrophic factor (BDNF)[80]. BDNF fosters neurogenesis, an important prerequisite for an antidepressant response, and has been shown to be reduced by IL-1β and TNF and their downstream signalling pathways including NF-κB in stress-induced animal models of depression[81,82]. Increased levels of glutamate in the basal ganglia and dorsal ACC (dACC) — as measured by magnetic resonance spectroscopy (MRS) — have been described in patients receiving IFNα, and higher levels of glutamate correlated with an increase in depressive symptoms[83]. More recent data indicate that in patients with depression, increased inflammation as reflected by a CRP >3 mg L^{-1} is also associated with increased basal ganglia glutamate (compared with patients with a CRP <1 mg L^{-1}) that correlated with anhedonia and decreased psychomotor speed[84]. Interestingly, blocking glutamate receptors with ketamine or inhibiting IDO activity protects mice from LPS- or stress-induced depressive-like behaviour but leaves the inflammatory response intact[85,86]. These results indicate that increased activation of glutamate receptors by glutamate and/or quinolinic acid may be a common pathway through which inflammation causes depressive-like behaviour, suggesting that drugs that block glutamate receptor signalling and/or activation of the IDO pathway and its downstream metabolites might have unique applicability to patients with depression and increased inflammation. Importantly, conventional antidepressant medications act by increasing synaptic availability of monoamines and increasing neurogenesis through induction of BDNF[87]. Therefore, cytokines such as IL-1β and TNF serve to undermine these activities as they decrease the synaptic availability of monoamines while also decreasing BDNF and increasing extracellular glutamate, which is not a target of conventional antidepressant therapy. These cytokine-driven effects may explain the observations that increased inflammation is associated with less robust antidepressant treatment responses and that treatment-resistant patients exhibit increased inflammatory markers[88].

Effects of inflammation on neurocircuitry. Given the impact of cytokines on neurotransmitter systems that regulate the functional activity of neurocircuits throughout the brain, it is no surprise that neuroimaging studies have revealed cytokine-induced alterations in regional brain activity. Consistent with the evolutionary advantages of the partnership between the brain and the immune system, primary cytokine targets in the CNS involve those brain regions that regulate motivation and motor activity (promoting social avoidance and energy conservation) as well as arousal, anxiety and alarm (promoting hypervigilance and protection against attack) (FIG. 3).

Dopamine has a fundamental role in motivation and motor activity, and cytokines have been shown to decrease the release of dopamine in the basal ganglia in association with decreased effort-based motivation as well as reduced activation of reward circuitry in the basal ganglia, in particular the ventral striatum[89–91]. Inflammatory stimuli have been associated with reductions in reward responsiveness in the striatum across many neuroimaging platforms, demonstrating the validity and reproducibility of these cytokine-mediated effects on the brain in otherwise non-depressed individuals peripherally administered IFNα, endotoxin or typhoid vaccination and imaged by PET, functional magnetic resonance imaging (fMRI), MRS and quantitative magnetization transfer imaging[83,89,90,92,93]. Interestingly, recent fMRI studies suggest that inflammation-induced decreases in responsiveness to positive reward are also associated with increased sensitivity to aversive stimuli (that is, negative reinforcement) and reduced responsiveness to novelty in the substantia nigra (which is another dopamine-rich structure in the basal ganglia)[93,94]. Typhoid vaccination has also been shown to activate the subgenual ACC (sgACC), a brain region implicated in depression, and to decrease connectivity of the sgACC with the ventral striatum, an effect modulated by plasma IL-6 (REF. 26). These fMRI findings have recently been extended to patients with depression whose increased plasma CRP level is associated with decreased functional connectivity within reward-related circuits including the ventral striatum and the ventromedial prefrontal cortex that, in turn, mediates the relationship between CRP and anhedonia[95]. Indeed, patients with depression with a CRP >3 mg L^{-1} had little, if any, connectivity within reward-related circuits as measured by fMRI, whereas connectivity in patients with depression with a CRP <1 mg L^{-1} was similar to healthy controls[95]. Taken together, these data support the notion that the effect of cytokines on the brain in general and dopaminergic pathways in particular lead to a state of decreased motivation or anhedonia, which is a core symptom of depression.

fMRI studies have demonstrated that increased inflammation is also associated with increased activation of threat- and anxiety-related neurocircuitry, including the dACC as well as the insula and amygdala[26,96,97]. Of note, the dACC and amygdala are regions that exhibit increased activity in patients with high-trait anxiety and neuroticism[98], conditions that often accompany depression and are associated with increased inflammation. For example, increased concentrations of oral IL-6 and soluble TNF receptor 2 (also known as TNFRSF1B) in response to a public speaking stressor was significantly correlated with the response of the dACC to a social rejection task[97]. In addition, increased oral IL-6 expression in response to a social evaluation stressor was significantly correlated with activation of the amygdala, with subjects who exhibited the highest IL-6 responses to stress demonstrating the greatest connectivity within threat circuitry, including the amygdala and the dorsomedial prefrontal cortex, as measured by fMRI[99]. Interestingly, these data are consistent with the trafficking of monocytes to the amygdala during social defeat stress in mice[68].

Risk and resilience

Increased inflammation and the risk for depression. Consistent with the emerging recognition that inflammation may cause depression in certain subgroups of individuals, epidemiological studies on large community samples — as well as smaller samples of medically ill individuals — have demonstrated that increased inflammation serves as a risk factor for the future development of depression. For example, increased peripheral blood CRP and IL-6 concentrations were found to significantly predict depressive symptoms after 12 years of follow up in the Whitehall II study of over 3,000 individuals, whereas no association was found between the presence of depressive symptoms and subsequent blood CRP and IL-6 levels[100]. Similar findings were reported in the English Longitudinal Study of Ageing in which a CRP >3 mg L^{-1} predicted depressive symptoms and not vice versa[101]. Of note, however, some studies have found no longitudinal relationship between depression and inflammation, and others have found that depression leads to increased inflammation[102]. Other factors known to be associated with increased peripheral inflammation, including childhood and adult trauma, have also been shown to be predictive of a greater risk of developing depression[103,104].

Both genetic and epigenetic mechanisms may explain why childhood or adult traumas can contribute to exaggerated or persistent inflammation and, ultimately, depression. For example, polymorphisms in *CRP* were associated not only with increased peripheral blood concentrations of CRP but also with symptoms of post-traumatic stress disorder, especially heightened arousal, in individuals exposed to civilian trauma[32]. Moreover, gene–environment interactions have been found to influence depression severity in response to chronic interpersonal stress: individuals carrying polymorphisms in *IL1B* that are associated with higher expression of peripheral IL-1β exhibited more severe depressive symptoms in the context of interpersonal stress than individuals without the *IL1B* risk allele[105]. Similarly, mice in which peripheral blood leukocytes produced high concentrations of LPS-induced IL-6 *ex vivo* before stress exposure showed decreased social exploration after social defeat stress, whereas mice that produced low levels of IL-6 before stress exposure exhibited no behavioural effects in response to social defeat[88]. Of note, adoptive transfer of bone marrow progenitor cells from mice producing high levels of IL-6 *ex vivo* to mice that produced low levels of IL-6 made these formerly stress-resilient animals sensitive to the depressive effects of social defeat[88].

Epigenetic changes in genes related to inflammation may also affect the risk for depression and anxiety in the context of psychosocial stress. Indeed, the well-documented association of childhood trauma with increased inflammation is linked to stress-induced epigenetic changes in *FKBP5*, a gene implicated in the development of depression and anxiety as well as in the sensitivity to glucocorticoids[106]. Allele-specific, childhood trauma-dependent DNA demethylation in functional glucocorticoid response elements of *FKBP5* were found to be associated with decreased sensitivity of peripheral blood immune cells to the inhibitory effects of the synthetic glucocorticoid dexamethasone on LPS-induced production of IL-6 *in vitro*[106]. Of note, decreased activation of glucocorticoid receptor-responsive genes in association with increased activation of genes regulated by NF-κB has been found to be a 'fingerprint' of the effects of chronic stress in several studies examining a variety of psychosocial stressors[39,107].

T cells and resilience to depression. Some of the most intriguing data regarding the role of the immune system in depression come from studies showing that T cells may protect against stress and depression in laboratory animals. For example, the adoptive transfer of T cells from animals exposed to chronic social defeat stress led to an antidepressant behavioural phenotype in stress-naive mice, which was associated with decreased pro-inflammatory cytokines in serum, a shift towards a neuroprotective M2 phenotype in microglia and increased neurogenesis in the hippocampus[108]. Similar results have been reported following acute stress in mice, in which effector T cell migration to the choroid plexus as a result of glucocorticoid induction of intercellular adhesion molecule 1 (ICAM1) expression in the choroid plexus was associated with reduced anxiety-like behaviour[109]. Mice with impaired release of glucocorticoids in response to stress were anxiety prone[109]. Immunization of anxiety-prone animals with a CNS-specific antigen restored T cell trafficking to the brain during stress and reversed anxiety-like behaviour in association with increased neurogenesis[109]. Immunization with a CNS-specific antigen also blocked stress-induced depression in mice[110]. The mechanism by which T cells influence resilience is believed to be related to their production of IL-4 within the meningeal space. Through as yet uncharacterized pathways, IL-4 then stimulates astrocytes to produce BDNF, and also promotes the conversion of meningeal monocytes and macrophages from a pro-inflammatory M1 phenotype to a less inflammatory M2 phenotype[111]. The movement of T cells throughout the brain, including the meningeal space, has become an area of special interest with the recent description of a brain lymphatic system that heretofore had gone unrecognized[112]. Data also indicate that T_{Reg} cells may have a role in reducing inflammation and supporting neuronal integrity during stress[113]. Similar reports have characterized T cells that are activated by vagal nerve stimulation to produce acetylcholine, which can inhibit NF-κB activation by binding to the α7 subunit of the nicotinic acetylcholine receptor[114].

Relevant to depression, however, peripheral T cell trafficking in response to glucocorticoids has been shown to be impaired in patients with depression, possibly owing to glucocorticoid resistance as a result of genetically mediated (for example, *FKBP5*) or inflammasome-mediated mechanisms targeting the glucocorticoid receptor[46,115]. In addition, inflammatory cytokines and their signalling pathways, including p38 MAPK, have direct inhibitory effects on glucocorticoid receptor function[116]. Moreover, patients with depression have been shown to have increased numbers of peripheral blood myeloid-derived suppressor cells, which inhibit T cell function[117]. Of note,

Myeloid-derived suppressor cells
A heterogeneous population of cells of myeloid origin that rapidly expands during inflammation and can potently suppress T cell responses. They are now being explored as potential therapeutic targets to inhibit immune responses in autoimmune disease or transplant rejection.

Box 2 | **Guidelines for anti-inflammatory clinical trials in depression**

Based on the animal and human literature on the effects of cytokines on the brain, the following guidelines can inform clinical trials designed to test the cytokine hypothesis of depression.

Inflammation only occurs in subgroups of patients with depression[30]. Clinical trials should enrich for patient populations with evidence of increased inflammation, particularly those identified by a C-reactive protein (CRP) >3 mg L^{-1}, which has been shown to characterize patients with depression with altered reward circuitry and increased basal ganglia glutamate, as well as those who have shown a response to anti-cytokine therapy[30,84,95].

Anti-inflammatory drugs may harm patients without increased inflammation. Inflammatory cytokines and the innate immune response have pivotal roles in synaptic plasticity, neurogenesis, long-term potentiation (which is a fundamental process in learning and memory) and possibly antidepressant response[123,128].

Primary behavioural outcome variables should include measures of anhedonia and anxiety. Neuroimaging studies coupled with studies administering a variety of inflammatory stimuli, including the inflammatory cytokine interferon-α, endotoxin and typhoid vaccination, have revealed that inflammation targets neurocircuits in the brain that regulate motivation and reward as well as anxiety, arousal and alarm[35]. In addition, these symptoms have been shown to respond to anti-cytokine therapy in limited studies.

Drugs that specifically target inflammatory cytokines and/or their signalling pathways are preferable. The majority of clinical trials to date have used anti-inflammatory drugs (non-steroidal anti-inflammatory agents and minocycline, a tetracycline antibiotic) that have several off-target effects making the extant data relevant to testing the cytokine hypothesis of depression difficult to interpret[31].

Target engagement must be established in the periphery and ultimately the brain. Protein and gene expression markers of inflammation in the peripheral blood can serve as relevant proxies for inflammation in the brain[129], especially given evidence of trafficking of activated peripheral immune cells to the brain in stress-induced animal models of depression. Relevant therapeutic interventions should decrease peripheral inflammatory markers in concert with improvement of specific depressive symptoms. Translocator protein neuroimaging ligands may ultimately serve as direct measures of neuroinflammation and its inhibition by anti-inflammatory therapies in future clinical trials[61].

activation of the NLRP3 inflammasome leads to increased accumulation of myeloid-derived suppressor cells[118]. Decreased numbers of peripheral blood T_{Reg} cells and reduced concentrations of anti-inflammatory cytokines in the blood, including TGFβ and IL-10, have also been reported in depression[119]. Thus, it appears that patients with depression may have impairments in neuroprotective and anti-inflammatory T cell responses.

These findings suggest that therapies that boost such T cell responses could be used in patients with depression. Examples include immunization strategies (with CNS antigens as discussed above) that attract T cells to the brain or administration of bacteria, such as *Mycobacterium vaccae,* or parasites that stimulate T_{Reg} cell responses or T cell production of IL-4 (REFS 14,109,110,120). Indeed, colonization of pregnant dams with helminths attenuated the increase of hippocampal IL-1β in neonatal rats infected with bacteria and protected these animals from the subsequent development of microglial sensitization and cognitive dysfunction in adulthood. This effect was associated with increased *ex vivo* production of IL-4 and decreased production of IL-1β and TNF by splenic macrophages in response to LPS stimulation[120]. Finally, vagus nerve stimulation could be used to induce anti-inflammatory acetylcholine-producing T cells[121]. Although many strategies exist to activate anti-inflammatory T cell responses including the induction of T_{Reg} cells by administration of mesenchymal stem cells[122], the majority of the approaches discussed above have proof-of-concept data in animal models of depression. Nevertheless, the clinical relevance of these approaches has yet to be determined by randomized clinical trials in patients with depression.

Cytokine hypothesis of depression
A theoretical framework that suggests that cytokines have a primary role in alterations of neurotransmitter metabolism, neuroendocrine function, neuroplasticity, neurocircuitry and behaviour in a subgroup of patients with depression and increased inflammation.

Translational considerations

Our increasing understanding of how inflammatory processes contribute to depression, combined with the growing frustration over the lack of discovery of new antidepressants, have stimulated interest in the possibility that various classes of anti-inflammatory medications or other anti-inflammatory strategies (as discussed above) may hold promise as novel 'all-purpose' antidepressants. Unfortunately, it appears that anti-inflammatory agents may only demonstrate effective antidepressant activity in subgroups of patients who show evidence of increased peripheral inflammation, for example individuals with medical conditions including osteoarthritis and psoriasis that are characterized by increased levels of peripheral inflammation and patients with depression with increased inflammatory markers[29,30]. Moreover, in patients with depression who do not show elevated peripheral levels of inflammation, anti-inflammatory treatments may actually impair placebo responses that contribute to the effectiveness of all known antidepressant modalities[123]. In the only study to date examining the antidepressant effect of a cytokine antagonist in medically healthy adults with treatment-resistant depression, post hoc analysis revealed a dose-response relationship between baseline levels of peripheral inflammation and subsequent antidepressant response to the TNF inhibitor infliximab[30]. In patients with baseline plasma CRP concentrations ≥5 mg L^{-1}, infliximab outperformed placebo with an effect size similar to that observed in studies of standard antidepressants. Patients with a CRP >3 mg L^{-1}, the standard cut-off for high inflammation, also exhibited separation from placebo. Of note, this latter finding along with data demonstrating the relevance of a CRP >3 mg L^{-1} to altered reward circuitry and glutamate metabolism in depression as well as the prediction of subsequent depressive episodes (described above) aligns well with other diseases in which a CRP >3 mg L^{-1} is relevant to prediction and pathology including cardiovascular disease and diabetes. These data suggest that the cut-off for high inflammation in depression may be consistent with other disorders (BOX 2). Importantly, however, in patients with lower levels of inflammation, blockade of TNF with infliximab actually impaired the placebo response[30], suggesting that anti-inflammatory treatments in patients without inflammation may be detrimental, highlighting the growing recognition that the immune system has an important role in several processes central to neuronal integrity.

We conclude by offering the balanced perspective that anti-inflammatory therapies are unlikely to be all-purpose antidepressants. Perhaps we only think of standard antidepressants as all-purpose agents because we have never succeeded in developing predictive biomarkers that would reliably inform us of who will respond to any given agent.

© 2015 Macmillan Publishers Limited. All rights reserved

If so, then we view these agents as all-purpose, not because it is true but out of hope and ignorance. Thus, instead of being a negative, perhaps the finding that baseline inflammatory biomarkers such as CRP can predict subsequent symptomatic response to anti-inflammatory strategies is, in fact, the most positive development thus far in our quest to understand how the immune system might be harnessed to improve the treatment of depression.

Conclusion

In ancestral times, integration of inflammatory responses and behaviours of avoidance and alarm provided an evolutionary advantage in managing the microbial world. In the absence of the temporizing influence of commensal organisms that were rife in environments in which humans evolved, the inflammatory bias of the human species in the civilized world has been increasingly engaged in the complex world of psychosocial interactions and the inevitable stress it engenders. Responding to these sterile insults with activation of the inflammasome and mobilization of myeloid cells to the brain, the resultant release of inflammatory cytokines impinges on neurotransmitters and neurocircuits to lead to behaviours that are poorly suited for functioning in modern society. This inevitability of our evolutionary past is apparent in the high rates of depression that are seen in society today. There is also an increasing recognition of mechanisms of resilience that derive from our emerging understanding of the neuroprotective effects of a variety of T cell responses ranging from effector T cells that produce IL-4 to T_{Reg} cells with anti-inflammatory properties. A better understanding of these neuroprotective pathways and of the inflammatory mechanisms — from inflammasome activation to cell trafficking to the brain — that operate in patients with depression may lead to the development of novel anti-depressant therapies.

This study provides some of the most compelling evidence that neuroinflammation occurs in major depression by demonstrating that monocytes traffic to the brain of patients with depressive symptoms and assume a perivascular localization in association with chemoattractant molecules such as CCL2, which has been shown to attract monocytes to the brain in animal models of stress.

This paper gives compelling evidence in laboratory animals that individual differences in the behavioural response to a social stressor is mediated by individual differences in the production of the inflammatory cytokine IL-6, suggesting that genetic and/or environmental factors that regulate inflammatory responses can determine stress-induced depressive-like behaviour.
89. Capuron, L. *et al.* Dopaminergic mechanisms of reduced basal ganglia responses to hedonic reward during interferon-α administration. *Arch. Gen. Psychiatry* **69**, 1044–1053 (2012).
Using multimodal neuroimaging, this report provides an integration of the impact of inflammatory cytokines on reward pathways and dopamine metabolism in the basal ganglia that leads to alterations in behaviours relevant to motivation and ultimately anhedonia — a core symptom of depression.

This neuroimaging study is the first to demonstrate that the impact of immune stimuli (for example, IFNα, typhoid vaccination and endotoxin) on the brains of otherwise non-depressed individuals extended to patients with depression, whose increased inflammation was found to reduce functional connectivity in reward-related neurocircuitry leading to anhedonia, a core symptom of depression.

Time-Restricted Feeding without Reducing Caloric Intake Prevents Metabolic Diseases in Mice Fed a High-Fat Diet

Megumi Hatori, Christopher Vollmers, Amir Zarrinpar, Luciano DiTacchio, Eric A. Bushong, Shubhroz Gill, Mathias Leblanc, Amandine Chaix, Matthew Joens, James A.J. Fitzpatrick, Mark H. Ellisman, and Satchidananda Panda

Inventory of Supplemental Information

Figure S1. Representative pictures of mice under different feeding regimens. Relates to Figure 1.

Figure S2. Restoration of normal metabolic activity and circadian clock in tRF. Relates to Figure 2.

Figure S3. Temporal patterns of gene expression in mice fed a normal diet. Relates to Figures 3, 4 and 6.

Figure S4. Hepatic nucleotide metabolites, free fatty acids and pro-inflammatory fatty acid. Relates to Figures 3 and 4.

Figure S5. Temporal pattern of hepatic gene expression in mice fed a NC or HF diet under *ad lib* and tRF paradigms. Relates to Figures 5 and 6.

Figure S6. Bile acid levels are increased in the liver of FT mice compared to those found in the FA mice. Related to Figure 6.

Figure S7. Relative levels and diurnal accumulation pattern of key metabolites in the mouse liver. Relates to Figures 2-4, 6 and 7.

Table S1. Liver metabolites and their relative abundance in mice fed NC or HF diet under *ad lib* and tRF regimens. Relates to Figures 2-4, 6 and 7.

Table S2. Major subcellular structures and their percent volume fraction in hepatocytes from FA and FT mice as determined by serial block face scanning electron microscopy of liver samples. Relates to Figure 5D.

Supplementary Figure 1

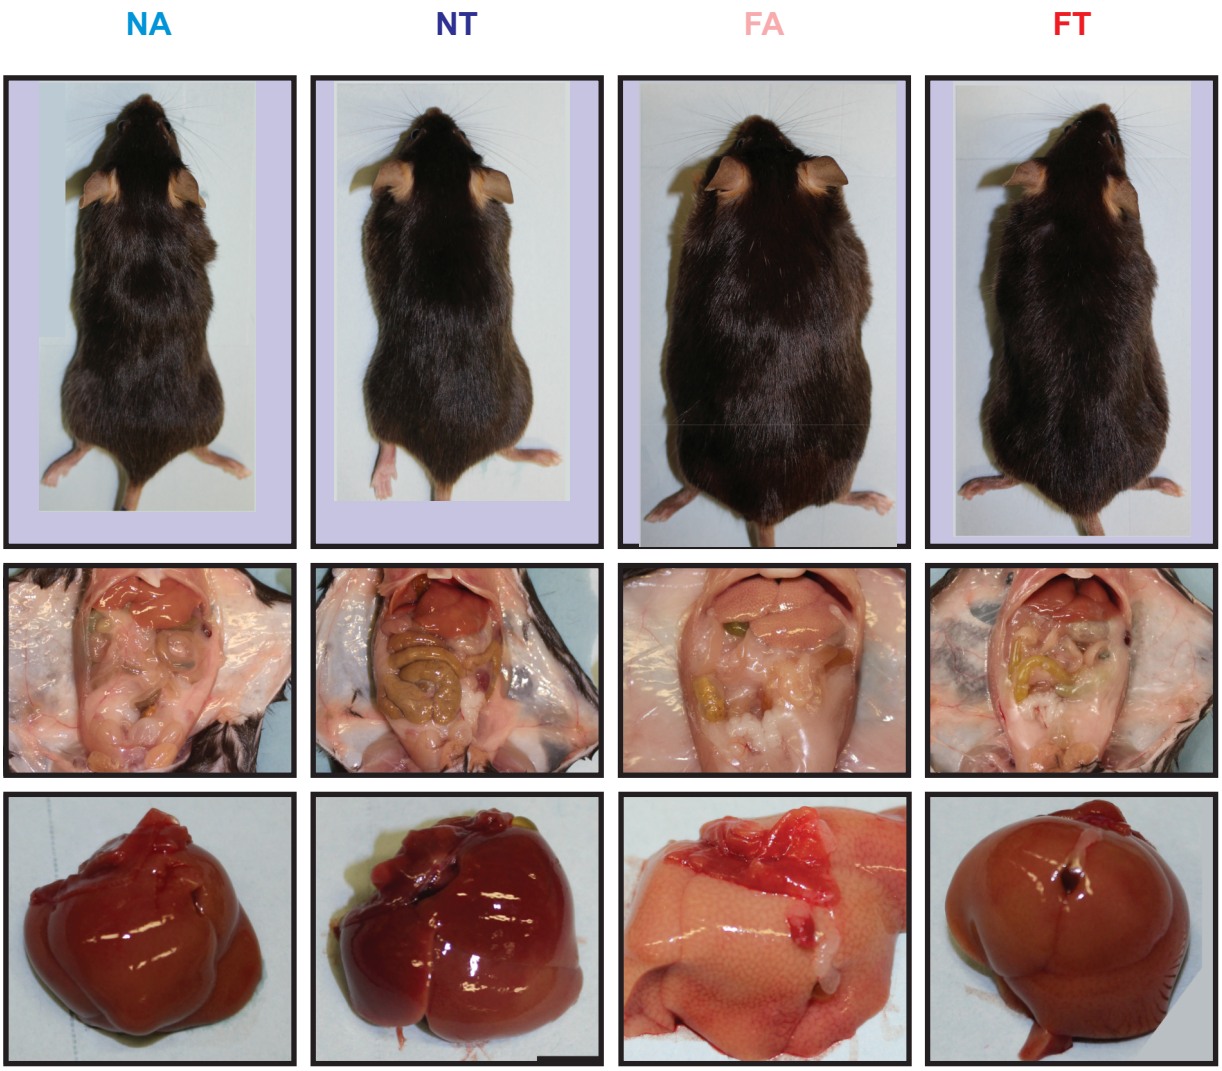

Figure S1. Pictures of randomly selected whole body (top), body cavity (middle) and liver (bottom) of mice on NA, NT, FA and FT regimens. Mice were sacrificed after 18 weeks on the feeding regimen. Relates to Figure 1.

Supplementary Figure 2

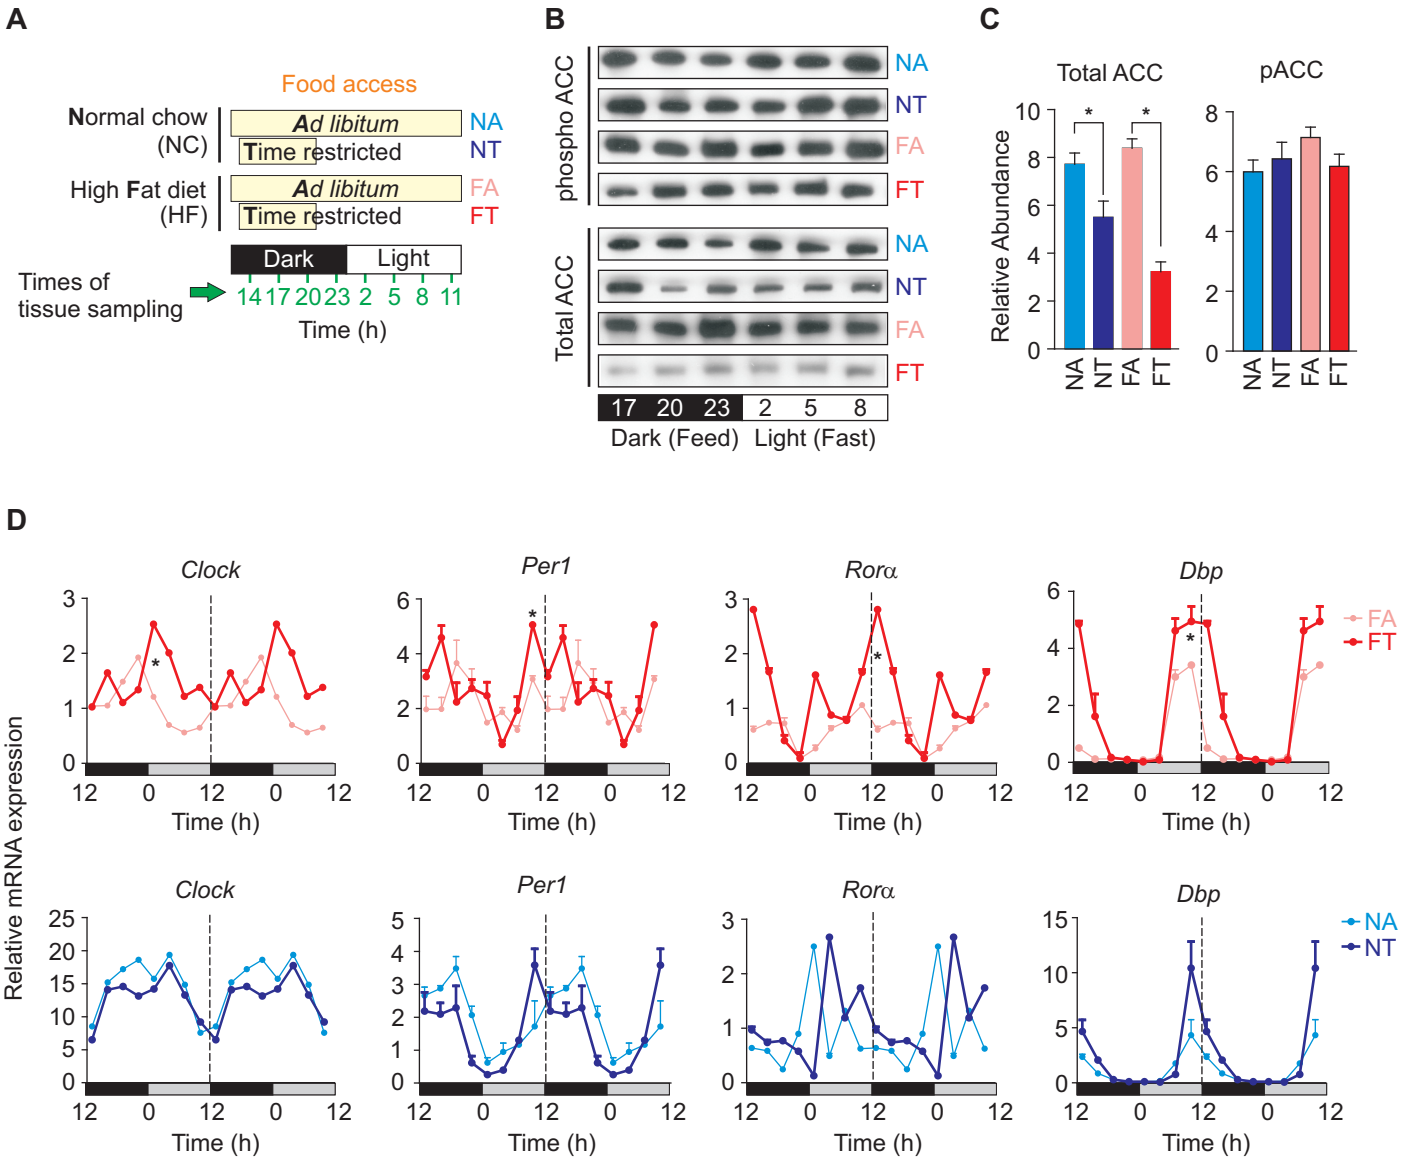

Figure S2. Time restricted feeding restored normal activities of metabolic regulators and circadian rhythms in mice fed a high fat diet. (A) Schematic representation of time of tissue samples collected for RNA, protein and metabolite analyses. At each time point, 4 mice under each feeding regimen were sacrificed, and their tissues collected and flash frozen for subsequent analyses. Each frozen tissue sample was pulverized to a fine powder and split for RNA extraction, protein extraction and metabolite analyses. For immuno blot analyses shown in Figures 2A, 2B and S2B, liver samples from three time points corresponding to the time of food access in tRF mice and three time points that are 12 h away during the day time were analyzed. **(B)** Immunoblot analyses of phospho-ACC (pACC) and total ACC from the liver of four groups of mice during nighttime feeding or daytime fasting. Equal quantities of protein were loaded in each lane. No apparent diurnal change in ACC or pACC was detected. **(C)** Densitometric quantification of average (+ SEM, n = 6) levels of total ACC and pACC in the livers of four groups of mice. The reduction in total ACC in the liver of mice under FT regimen is likely due to the increased expression of its repressor REV-ERBα (Feng et al., 2011). **(D)** Double-plotted mean (+ SEM, n = 4) mRNA levels of *Clock*, *Per1*, *Rorα* and *Dbp* from the liver show improved oscillation under tRF paradigm. The levels of expression and/or the peak:trough ratios are remarkably increased in FT relative to FA liver, while the changes are modest between NA and NT groups. Expression levels were measured by qRT-PCR and normalized against *Gapdh* mRNA. Results shown here relate to Figure 2.

Supplementary Figure 3

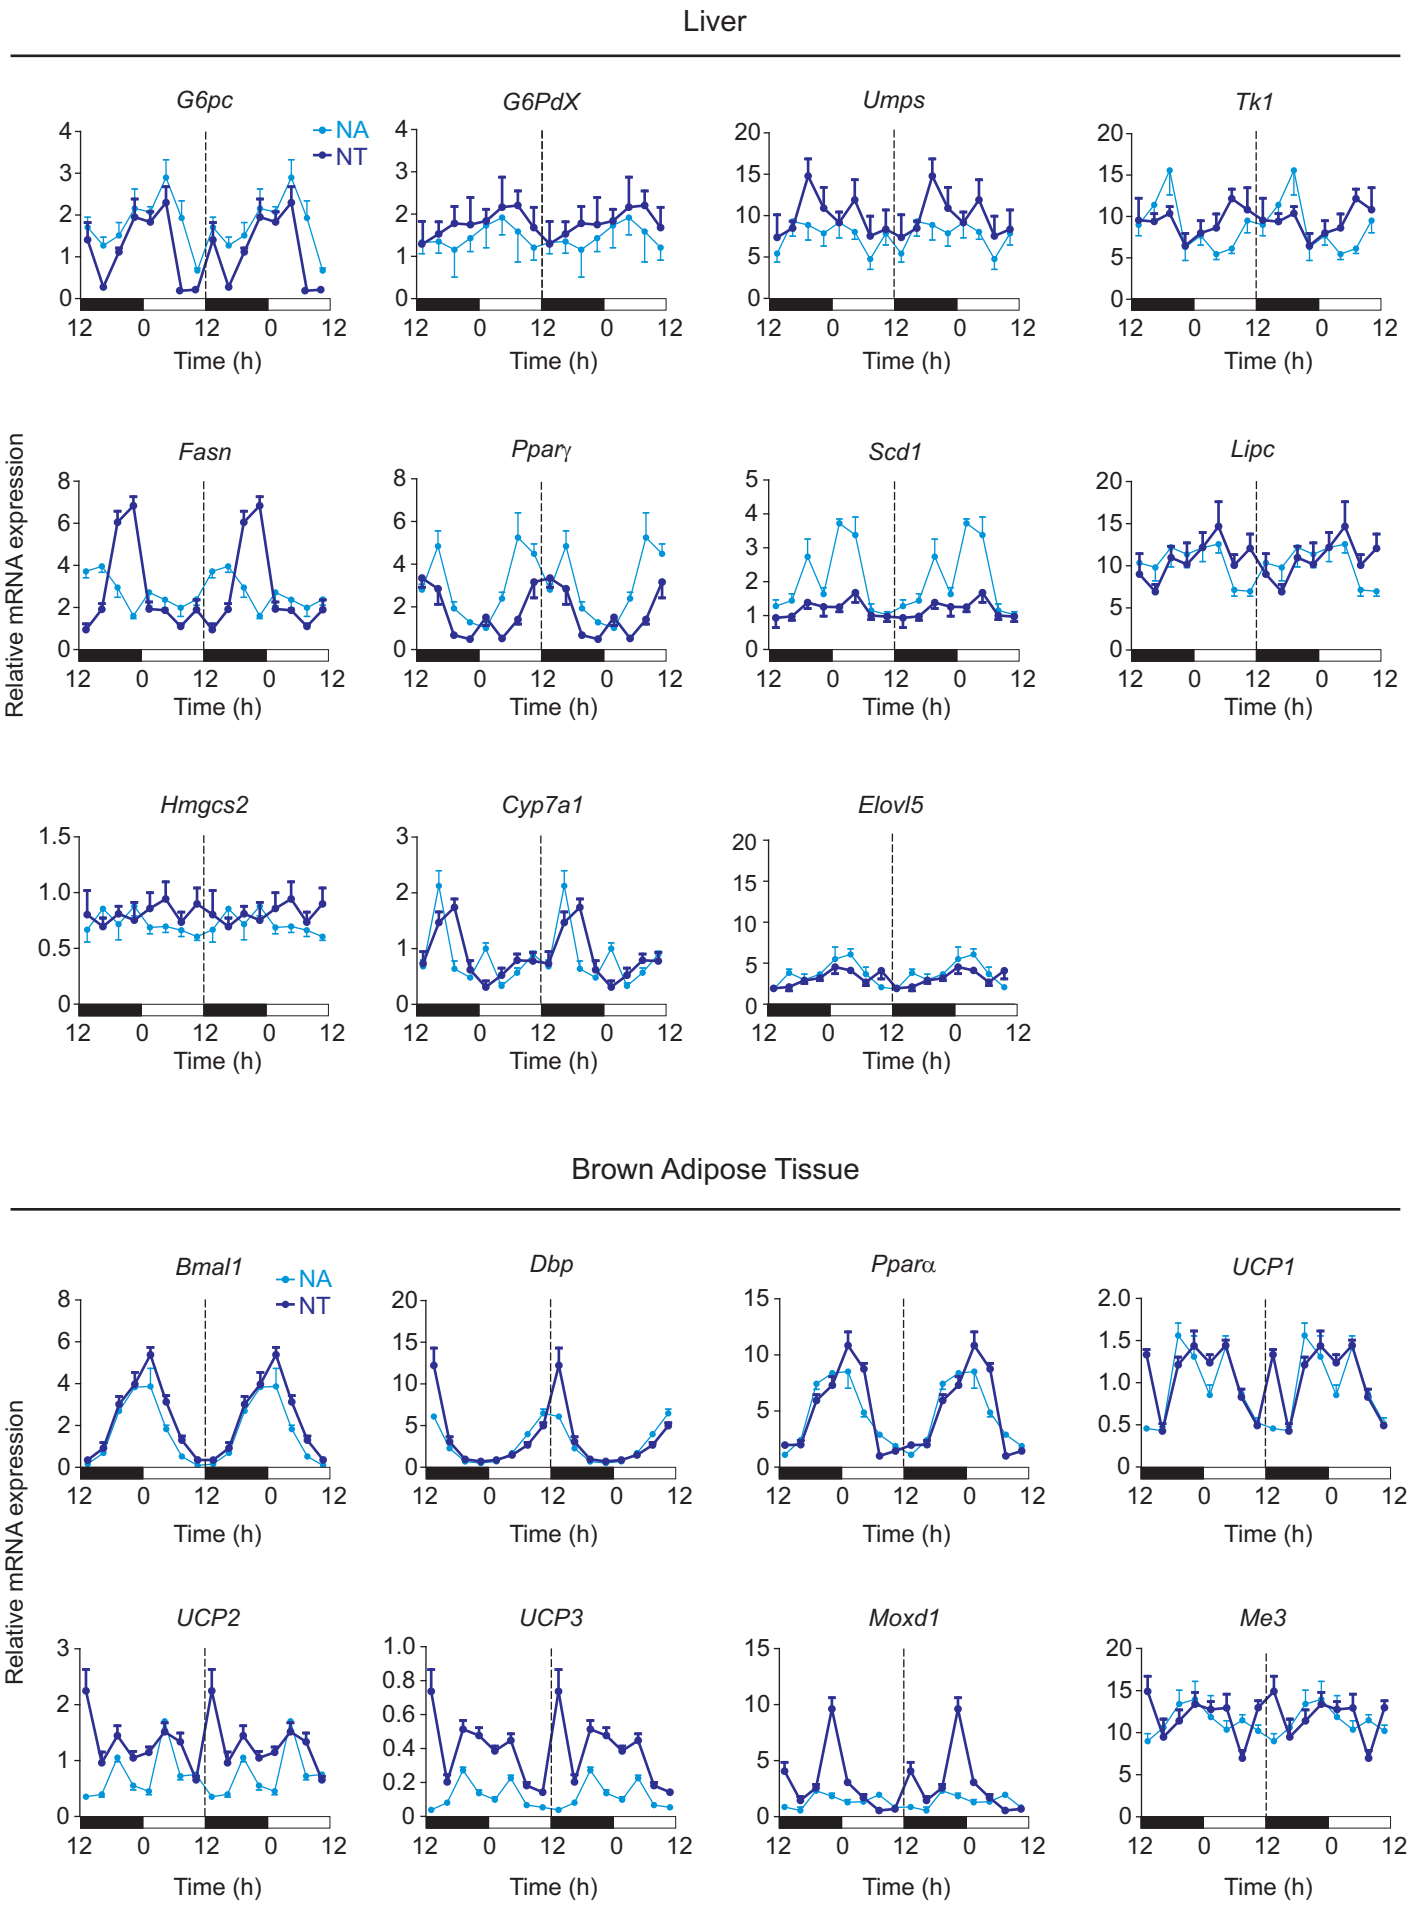

Figure S3. Temporal patterns of gene expression in mice fed a normal diet. Double-plotted average (+ SEM, n = 4) mRNA levels of genes regulating metabolism of glucose, nucleotides, fatty acids, cholesterol and bile acids in the liver or of circadian oscillator components, regulators of fat metabolism and mitochondria function in the BAT of NA and NT mice at different times of the day. Transcript levels were measured by qRT-PCR, and normalized to *Gapdh* RNA levels. Broken line separates double plotted data. Results relate to Figures 3, 4, and 6.

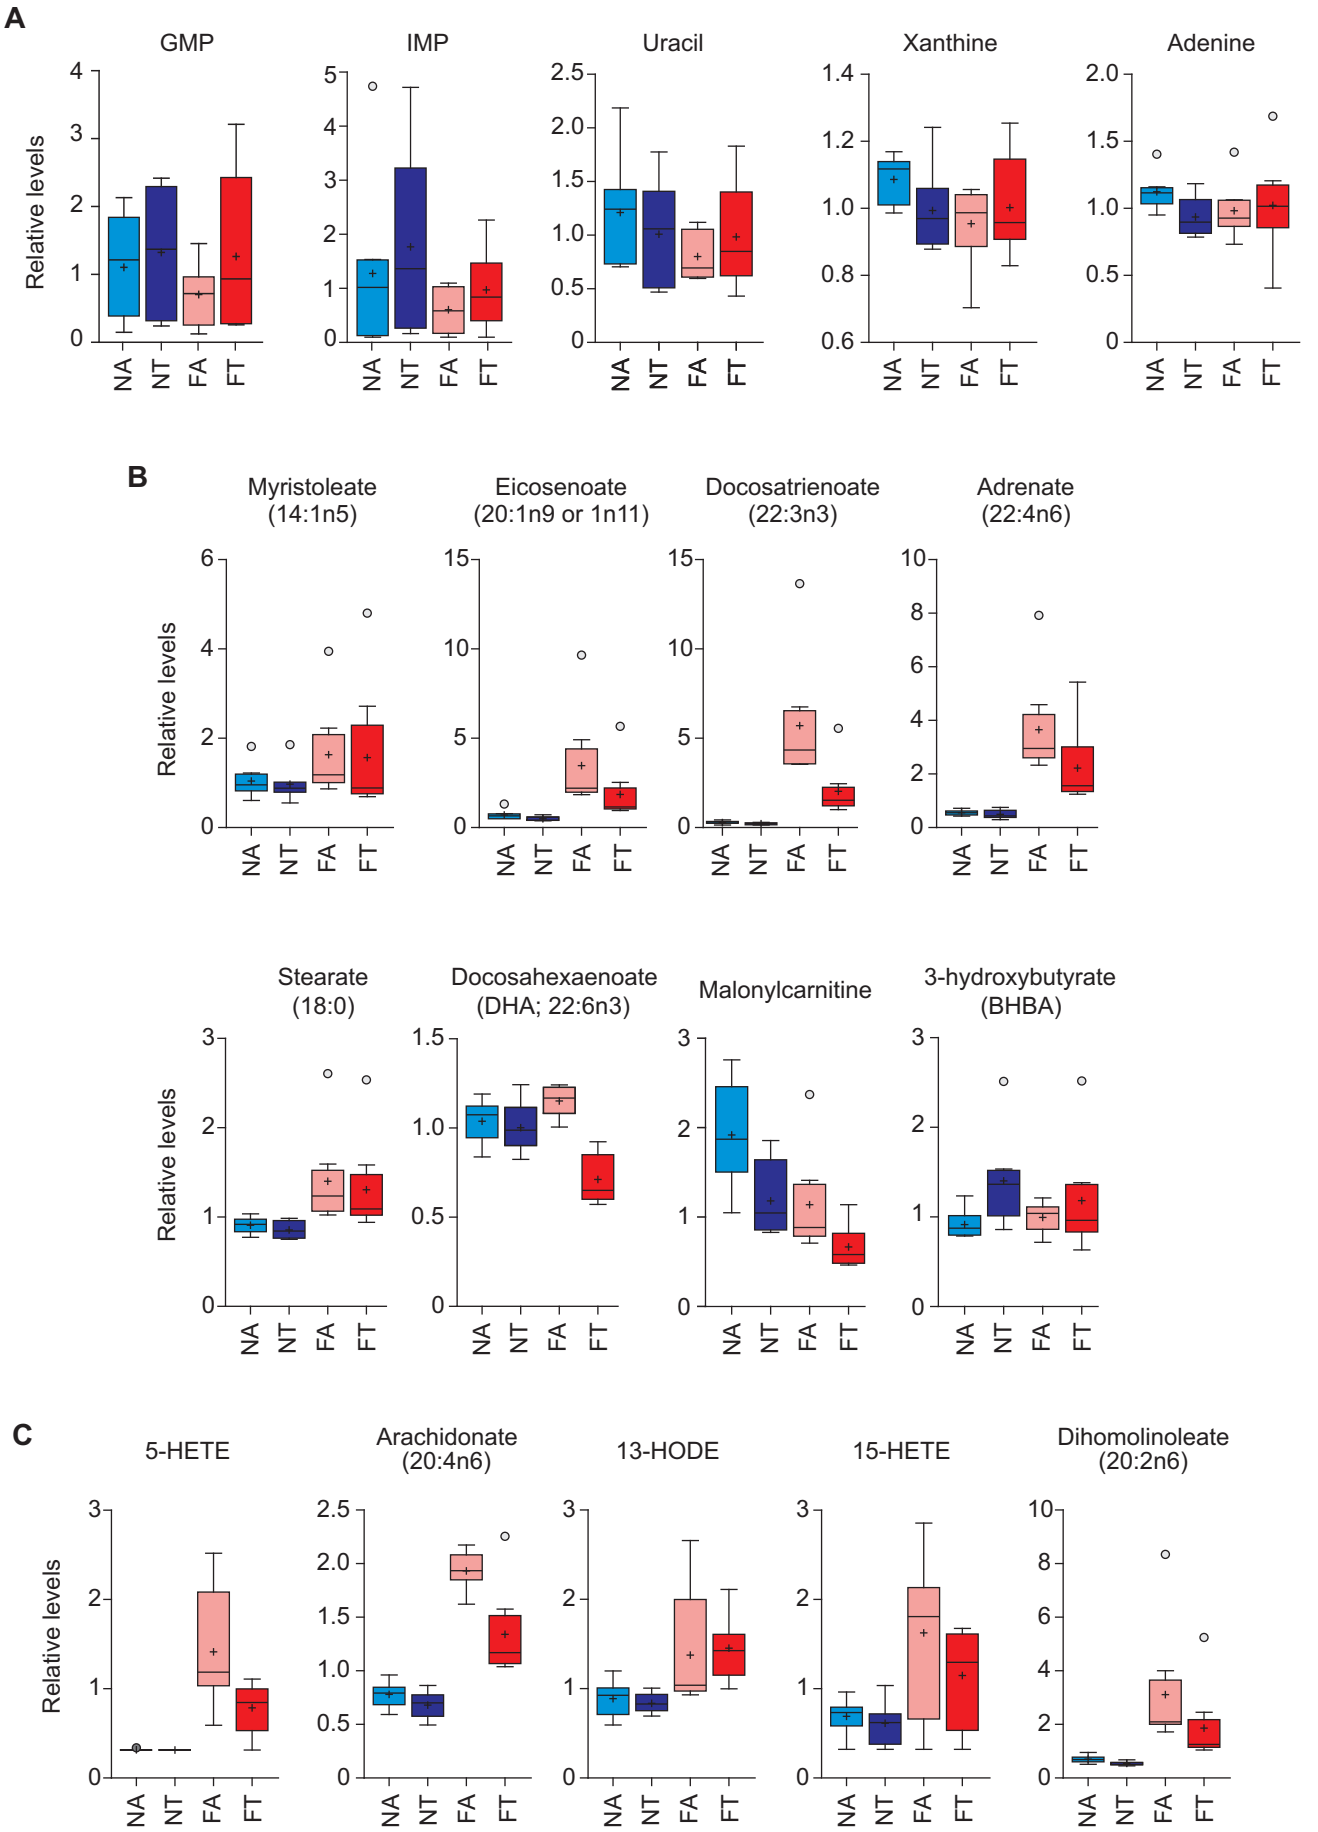
Supplementary Figure 4



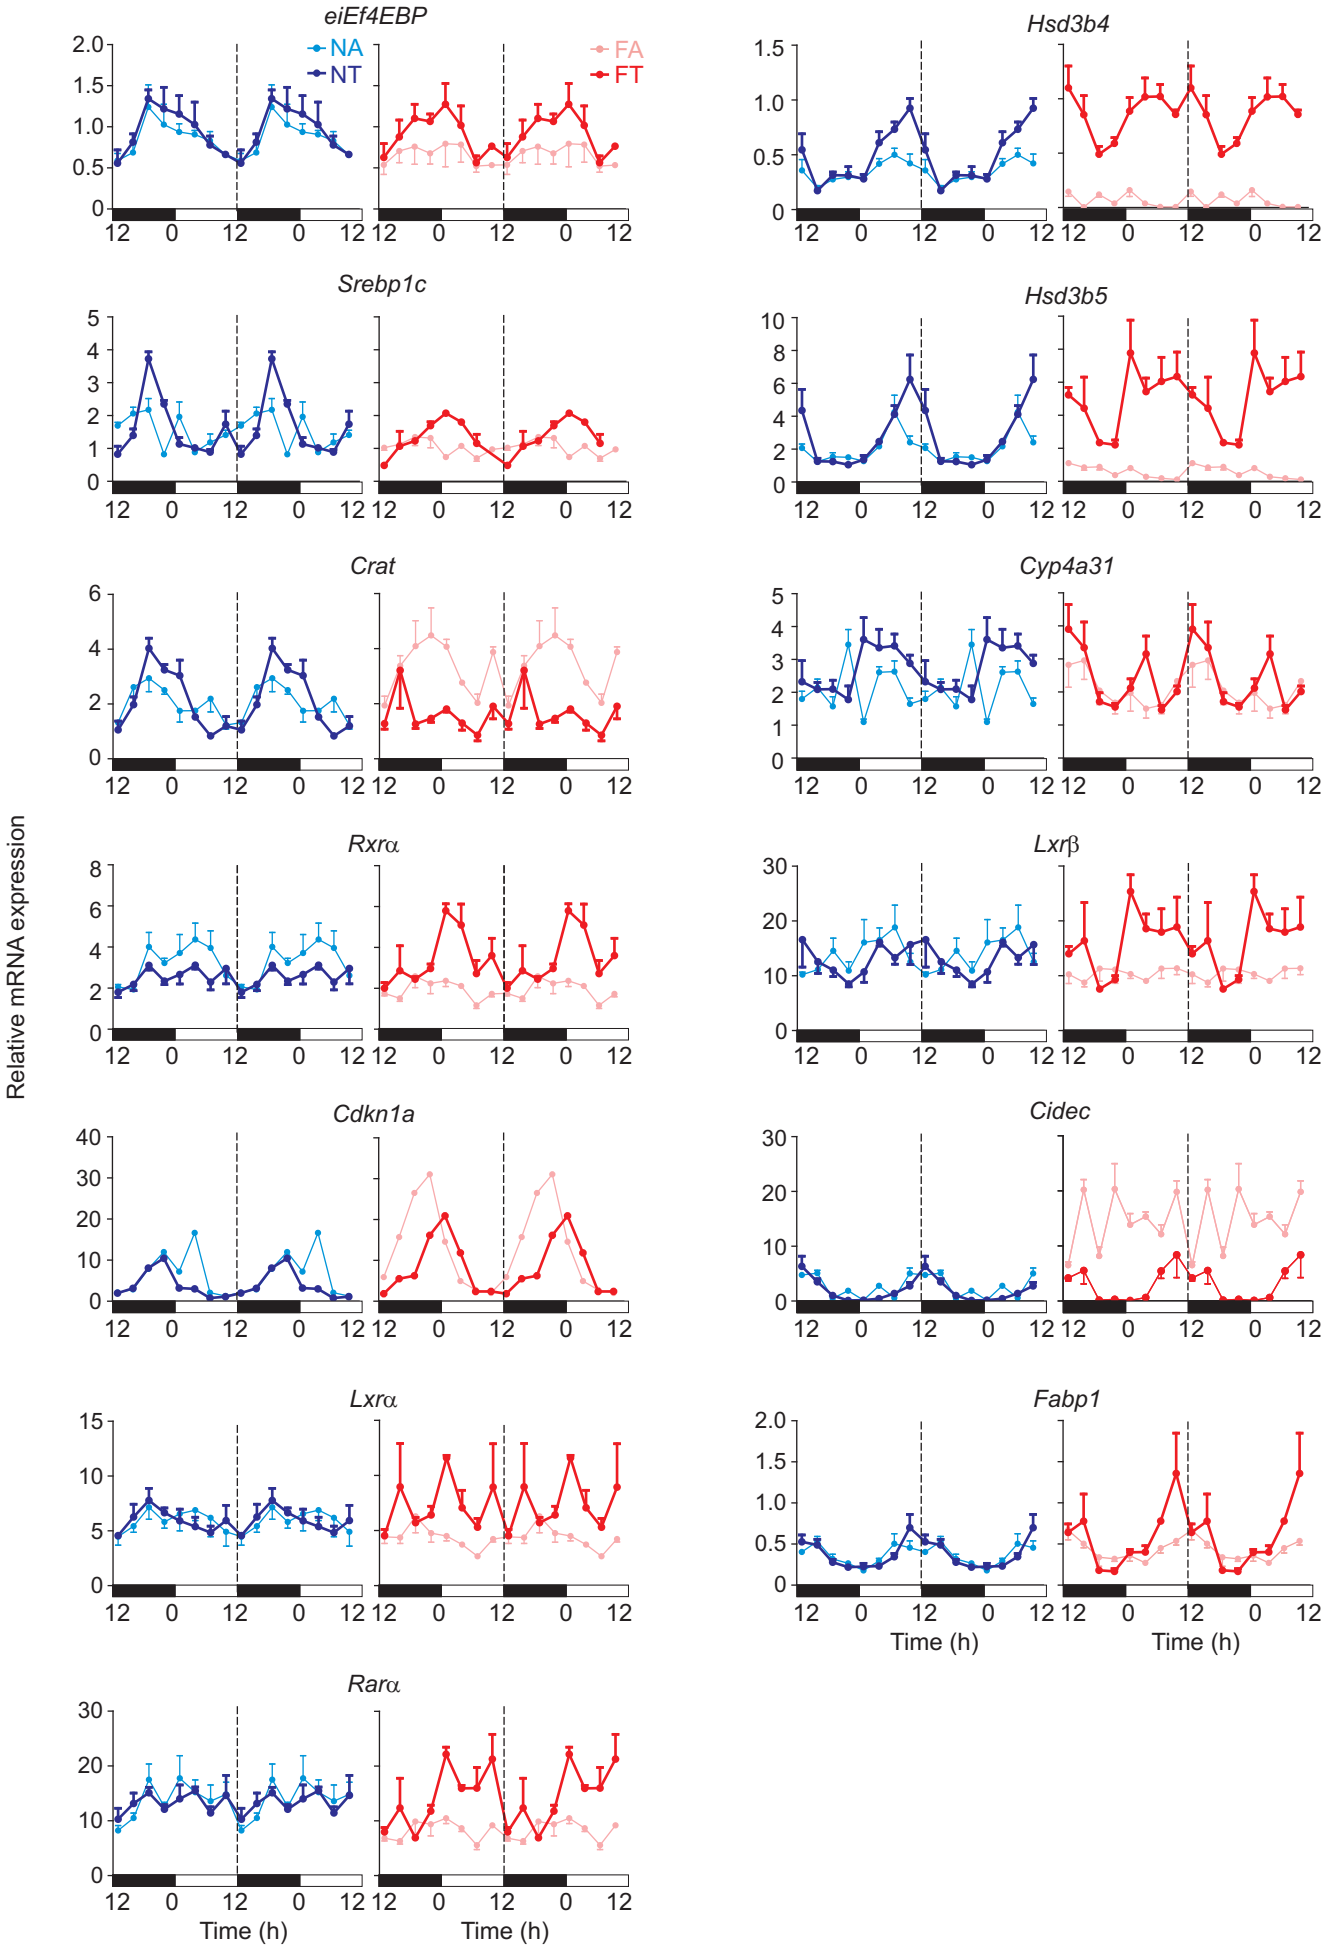


Figure S4. Hepatic accumulation of nucleotide metabolites, free fatty acids and pro-inflammatory fatty acid metabolites are modulated under tRF paradigm. (A) Levels of several intermediates of nucleotide metabolism are increased in the liver of FT mice relative to their levels in FA mice. This is consistent with the changes in gene expression and in nucleotide metabolites shown in Figures 3F-3H. **(B)** Relative levels of representative long chain free fatty acids are increased in mice fed high fat diet. The levels of the majority of long chain free fatty acids detected were reduced in the liver of FT mice. Mice fed normal chow generally contained small amount of free fatty acids. Nevertheless, the tRF paradigm further reduced the levels of hepatic free fatty acids. **(C)** Similar attenuation of pro-inflammatory fatty acids was observed in the liver. Results presented in Figure S4B and S4C relate to Figure 4. Results were plotted in whisker plots where the box denotes the middle 80 percentile with mean (+) and median (-). Error bars denote maximum and minimum of distribution with extreme data points marked (o).

Supplementary Figure 5

Supplementary Figure 5 (continued)

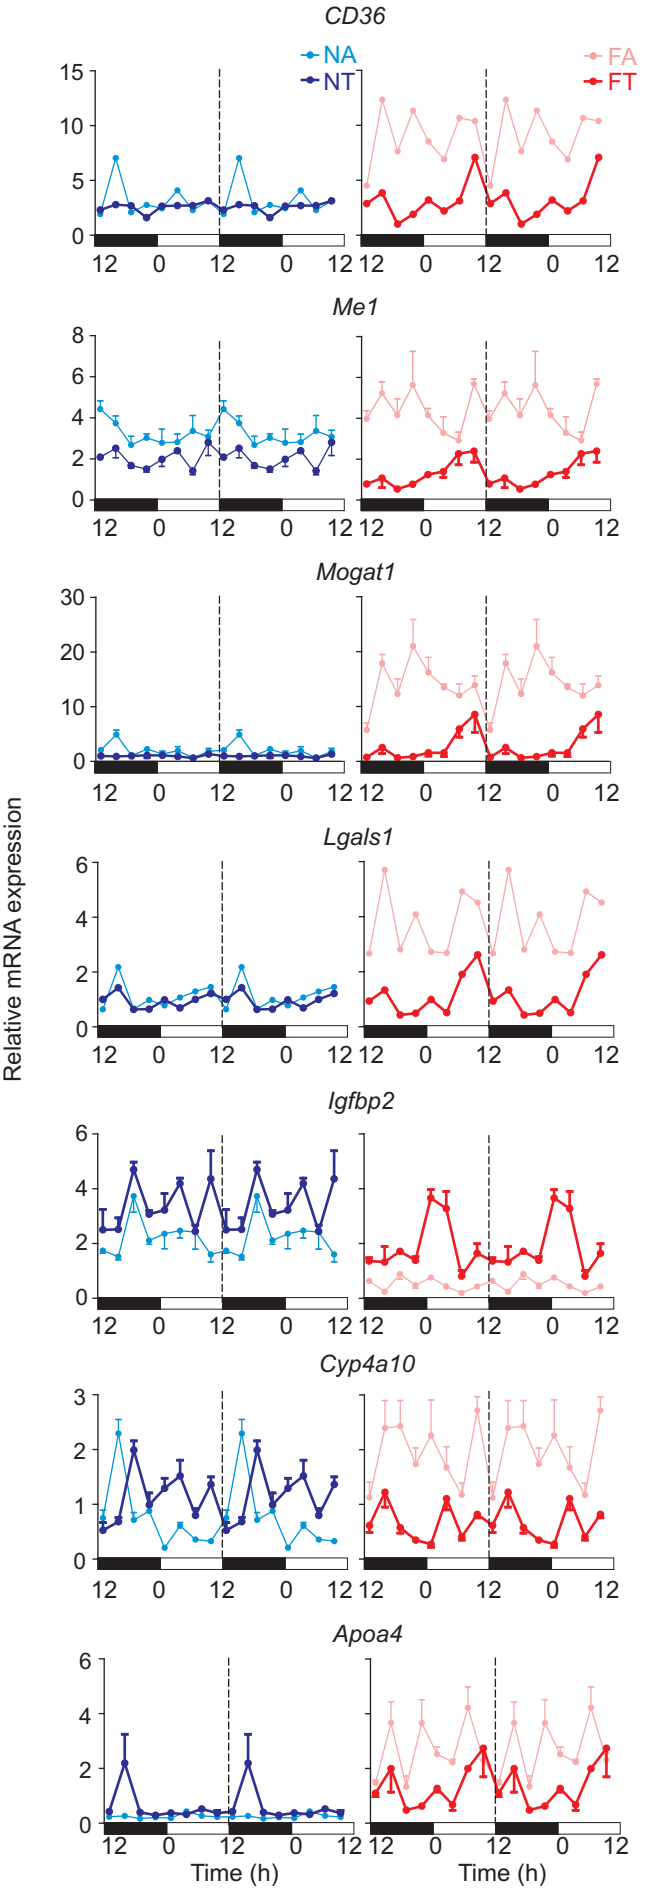

Figure S5. Temporal hepatic gene expression pattern in mice fed a NC or HF diet under *ad lib* and tRF paradigms. Double-plotted average (+ SEM, n = 4) mRNA levels of genes implicated in protein translation, steroid metabolism and in several liver diseases are shown. Transcript levels were measured by qRT-PCR, normalized to *Gapdh* RNA levels. Broken line separates double plotted data. Note that the overall changes in gene expression upon time restricted feeding are moderate in mice fed a normal diet, while temporal feeding pattern has a pronounced effect when mice are fed a high fat diet. Results relate to Figures 5 and 6.

Supplementary Figure 6

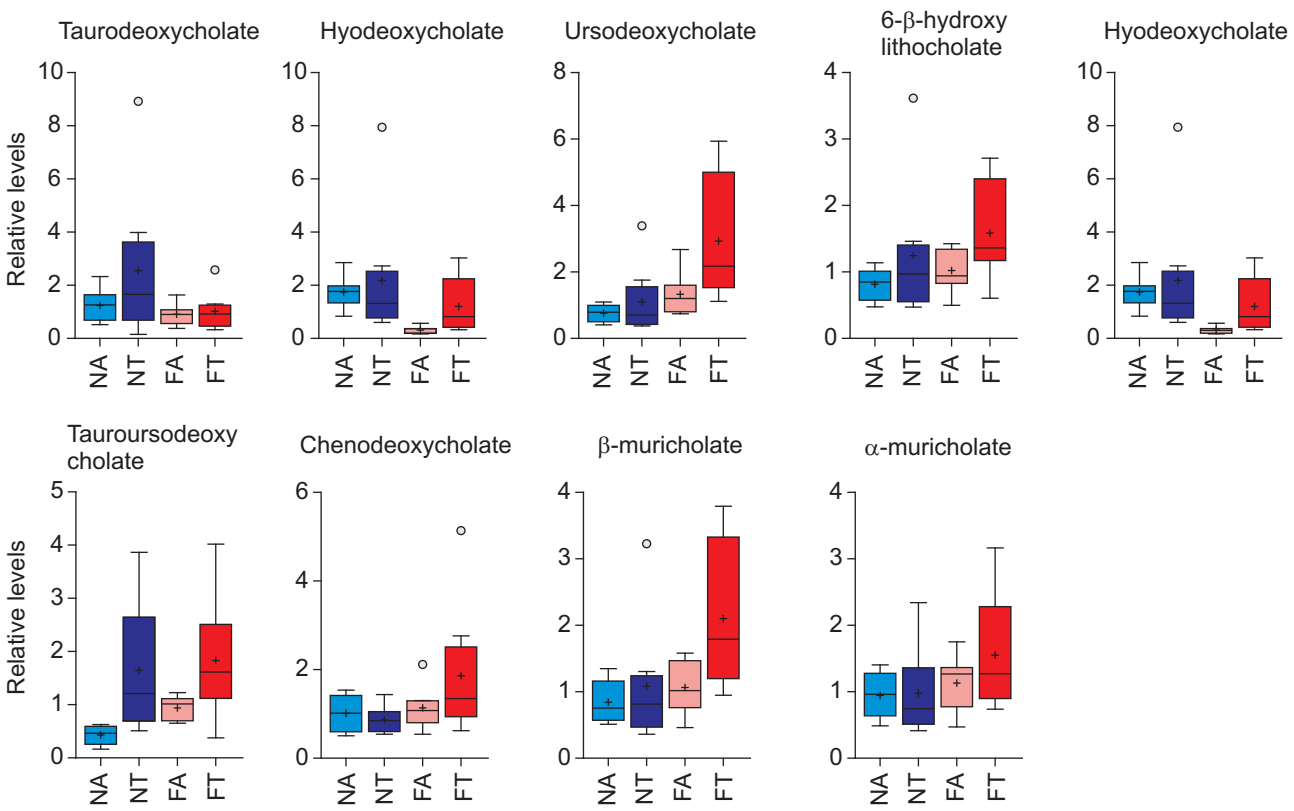

Figure S6. Bile acid levels are increased in the liver of FT mice compared to those found in the FA mice. Results were plotted in whisker plots where the box denotes the middle 80 percentile with mean (+) and median (-). Error bars denote maximum and minimum of distribution with extreme data points marked (o). Related to Figure 6.

Supplementary Figure 7

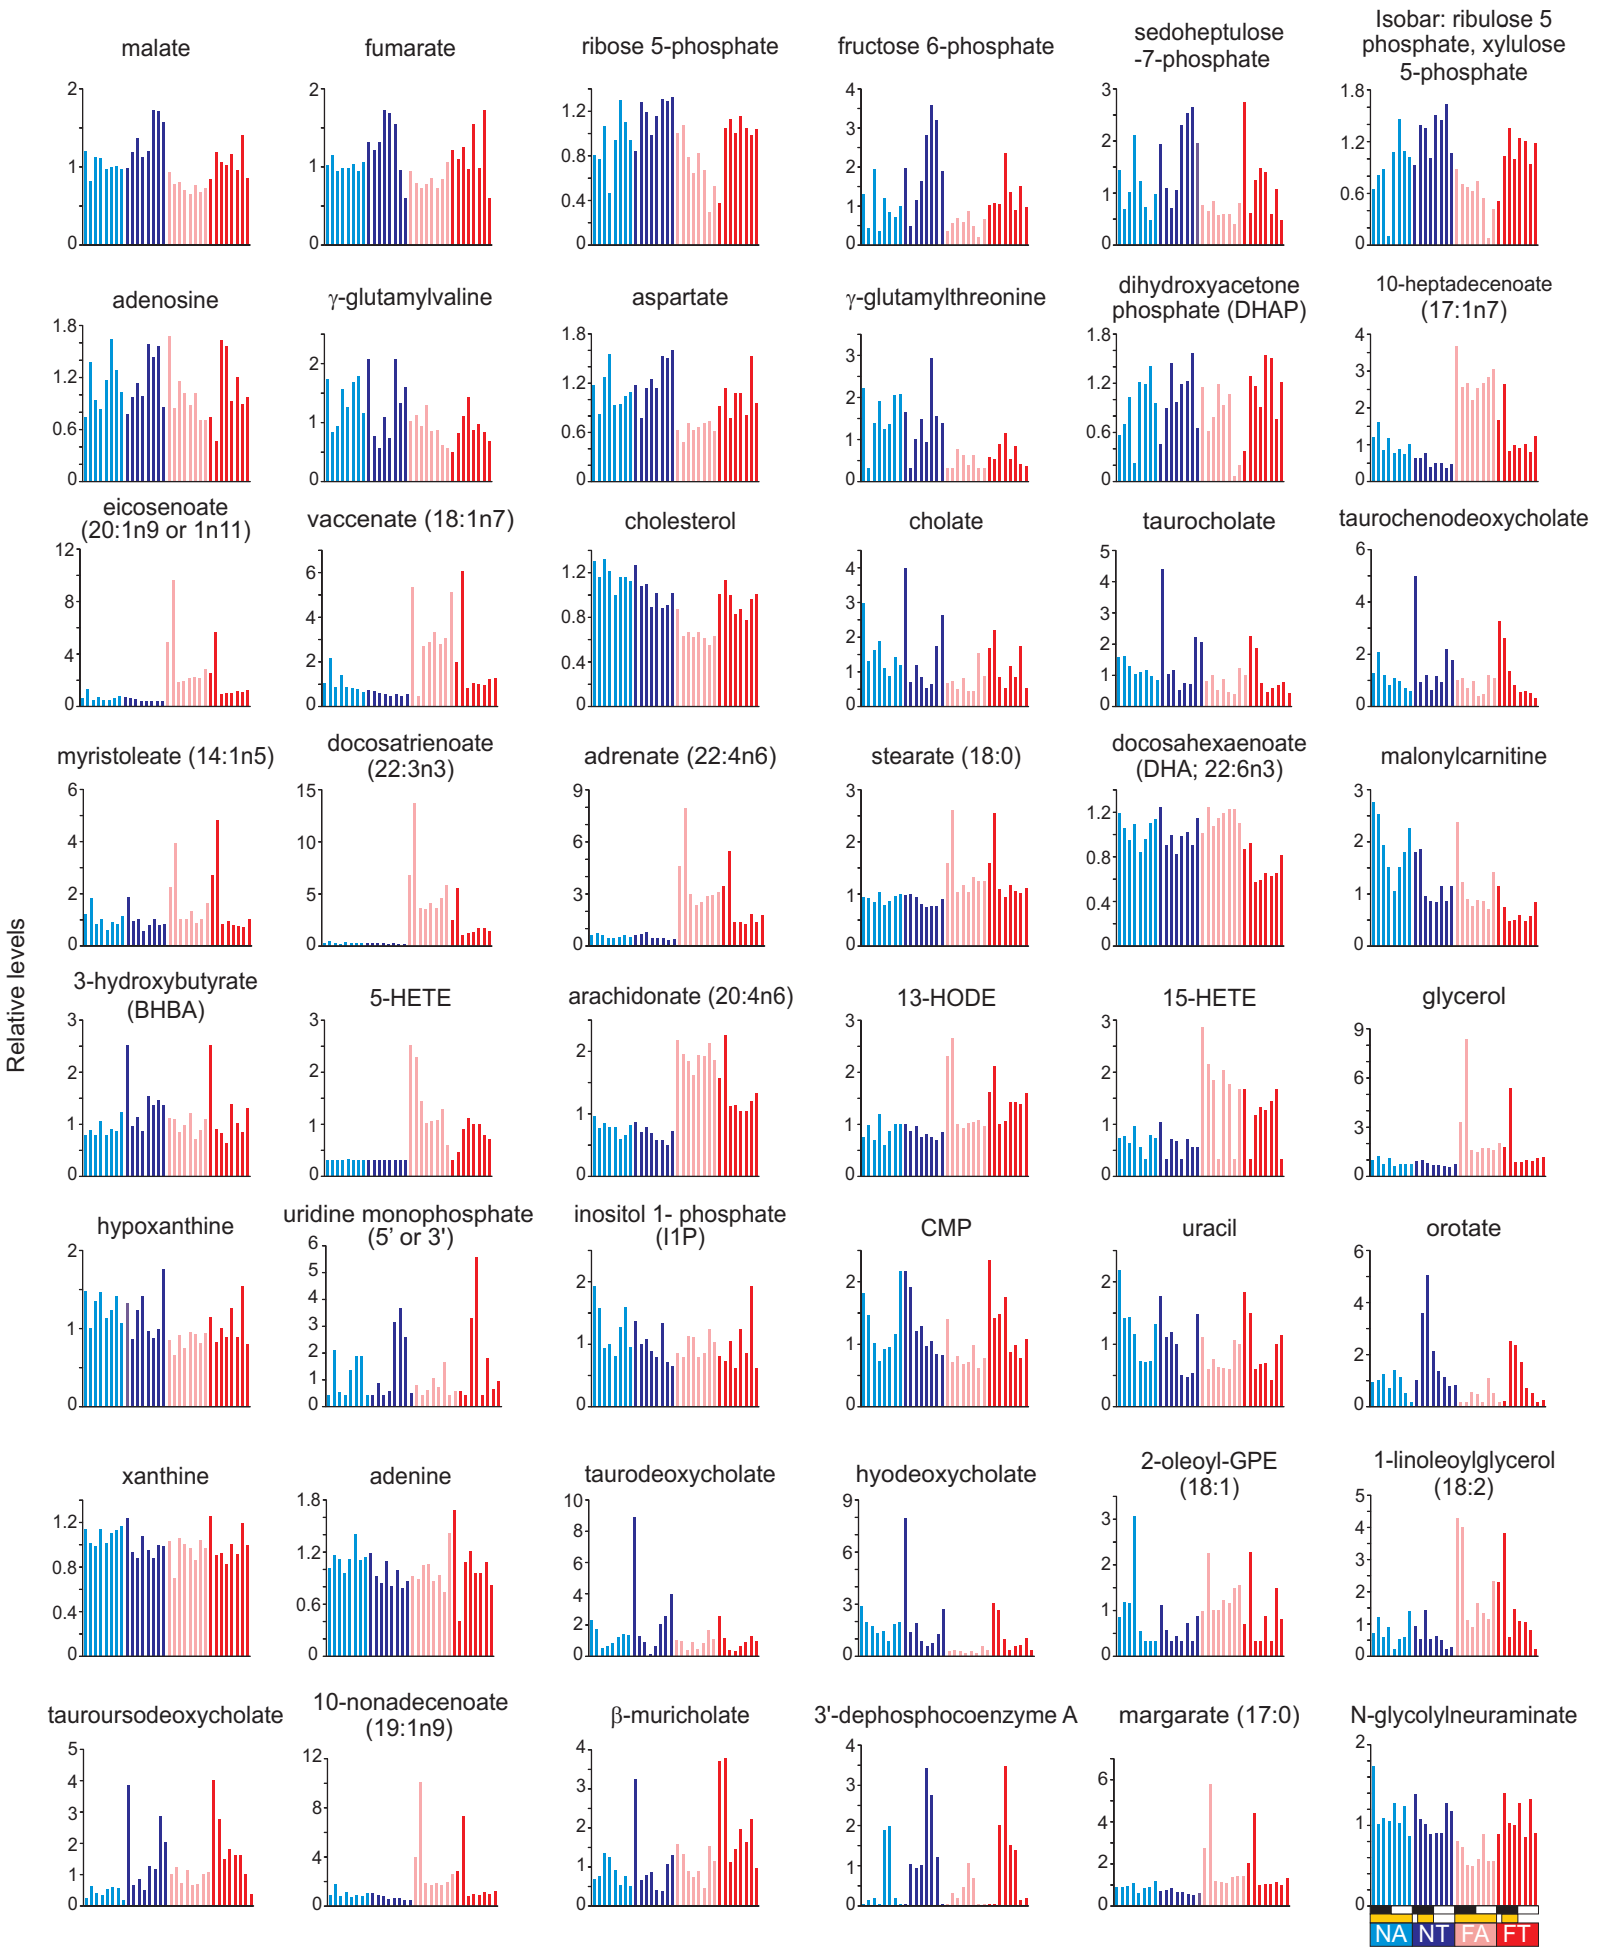

Figure S7. **Relative levels and the diurnal accumulation pattern of key liver metabolites in the mouse liver are defined by nutrient type and time of feeding.** Normalized levels of several metabolites at 8 different time points spaced 3 h apart over one full day are shown for each of the four feeding groups (NA, NT, FA and FT). Times of measurement relative to light:dark cycle and periods of food access are shown at the bottom right panel. Values shown here relate to the whisker plots of metabolites shown in Figures 2-4, 6 and 7. Relative values and associated statistical parameters are shown in Table S1.

Table S2

	Percentage of volume	
	FT	FA
Mitochondrion	19.92%	8.24%
Cytosol	33.56%	24.19%
Vacuole	2.80%	16.05%
Nucleus	6.58%	2.60%
Capillaries	13.83%	8.57%
Glycogen	14.22%	5.75%
Lipid Body	0.58%	30.15%
Endoplasmic Reticulum	8.51%	4.45%

Table S2. Major subcellular structures and their percent volume fraction in hepatocytes from FA and FT mice as determined by serial block face scanning electron microscopy of liver samples. Relates to Figure 5D.

Supplemental Experimental Procedures

Histology and Electron Microscopy. Sections (6 µm) of formaldehyde fixed liver, WAT and BAT were stained following standard H&E. Liver sections were also stained using the Sirius Red method. H&E and Steatohepatitis was scored using a semi-quantitative method derived from Brunt *et al*. (Brunt et al., 2004) measuring the degree of steatosis (0-3), ballooning degeneration (0-2), lobular (0-3) and portal (0-2) inflammation and fibrosis (0-4). Histology sections were digitally imaged using a fixed, high-resolution Leica DFC420 digital camera mounted on a Leica DMLS microscope. A serial block-face scanning electron microscopy (SBFSEM) volume was collected from both FT and FA liver following protocols as previously described (Williams et al., 2011), using a Gatan 3View system installed on a Zeiss Sigma SEM. Volumes were 12,000 pixel x 12,000 pixel x 500 slices with voxel dimensions of 5.63 nm XY x 70 nm Z. Image analysis was performed using IMOD (http://bio3d.colorado.edu/imod/). Stereology was performed using a custom plug-in for IMOD.

Transcript, protein and metabolite analyses.

Anti-pACC, anti-ACC, anti-pS6 and anti-S6 antibodies were purchased from Cell Signaling Technologies (Cat No. 3661S, 3661S 4858S and 2217S, respectively). qRT-PCR primer sequence information is available upon request. For rhythmic transcripts, average expression (± SEM) from experimental replicates from each time point over 24 h are double plotted as a line chart.

Toward a Neuroimaging Treatment Selection Biomarker for Major Depressive Disorder

Callie L. McGrath, BA; Mary E. Kelley, PhD; Paul E. Holtzheimer III, MD; Boadie W. Dunlop, MD; W. Edward Craighead, PhD; Alexandre R. Franco, PhD; R. Cameron Craddock, PhD; Helen S. Mayberg, MD

Importance: Currently, fewer than 40% of patients treated for major depressive disorder achieve remission with initial treatment. Identification of a biological marker that might improve these odds could have significant health and economic impact.

Objective: To identify a candidate neuroimaging "treatment-specific biomarker" that predicts differential outcome to either medication or psychotherapy.

Design: Brain glucose metabolism was measured with positron emission tomography prior to treatment randomization to either escitalopram oxalate or cognitive behavior therapy for 12 weeks. Patients who did not remit on completion of their phase 1 treatment were offered enrollment in phase 2 comprising an additional 12 weeks of treatment with combination escitalopram and cognitive behavior therapy.

Setting: Mood and anxiety disorders research program at an academic medical center.

Participants: Men and women aged 18 to 60 years with currently untreated major depressive disorder.

Intervention: Randomized assignment to 12 weeks of treatment with either escitalopram oxalate (10-20 mg/d) or 16 sessions of manual-based cognitive behavior therapy.

Main Outcome and Measure: Remission, defined as a 17-item Hamilton Depression Rating Scale score of 7 or less at both weeks 10 and 12, as assessed by raters blinded to treatment.

Results: Positive and negative predictors of remission were identified with a 2-way analysis of variance treatment (escitalopram or cognitive behavior therapy) × outcome (remission or nonresponse) interaction. Of 65 protocol completers, 38 patients with clear outcomes and usable positron emission tomography scans were included in the primary analysis: 12 remitters to cognitive behavior therapy, 11 remitters to escitalopram, 9 nonresponders to cognitive behavior therapy, and 6 nonresponders to escitalopram. Six limbic and cortical regions were identified, with the right anterior insula showing the most robust discriminant properties across groups (effect size = 1.43). Insula hypometabolism (relative to whole-brain mean) was associated with remission to cognitive behavior therapy and poor response to escitalopram, while insula hypermetabolism was associated with remission to escitalopram and poor response to cognitive behavior therapy.

Conclusions and Relevance: If verified with prospective testing, the insula metabolism-based treatment-specific biomarker defined in this study provides the first objective marker, to our knowledge, to guide initial treatment selection for depression.

Trial Registration: Registered at clinicaltrials.gov (NCT00367341)

MAJOR DEPRESSIVE DISORDER (MDD) is a highly prevalent, disabling, and costly illness.[1-3] For a patient presenting with MDD, an antidepressant medication or evidence-based psychotherapy is currently recommended as first-line treatment.[4-7] However, fewer than 40% of patients achieve remission with initial treatment,[8,9] and choosing the "wrong" initial treatment has significant individual and societal costs due to continued distress, risk of suicide, loss of productivity, and wasted resources associated with 2 to 3 months of an ineffective treatment.[10,11] Given the public health consequences of inadequately treated depression, a clinical or biological marker to guide initial treatment selection for MDD could have major health and economic impact.[12]

In other areas of medicine, identification of markers to guide treatment has significantly improved clinical outcome. For

example, in cancer[13] and heart disease,[14] biomarkers are currently used to optimize initial treatment selection as well as guide treatment modifications with disease progression. Over the past several decades, a number of potential markers to guide antidepressant treatment have been investigated including clinical,[15] immune,[16] inflammatory,[17] endocrine,[18] genetic,[19-21] and imaging/electroencephalography[22-27] measures. Despite this extensive research, to our knowledge, no clinically useful marker to guide treatment selection has emerged.

In the process of developing a marker to guide antidepressant treatment selection, it is important to consider what qualities such a marker should have. Toward this goal, a nonspecific biomarker that predicts improvement regardless of treatment is not useful. Rather, a clinically meaningful and treatment-specific biomarker (TSB) should (1) predict an individual's improvement to a specific treatment and (2) predict nonresponse to an alternative treatment. Such a biomarker can only be identified in a study that assesses outcome to 2 or more different treatments.

Previous neuroimaging studies have suggested that pretreatment brain activity patterns can predict efficacy, but those studies have generally focused on a particular treatment.[26,27] For example, higher rostral cingulate and/or subgenual cingulate activity has been associated with greater improvement with antidepressant medications,[28,29] sleep deprivation,[30] and cingulotomy.[31] Comparisons of different treatments have thus far identified markers of response and nonresponse but not patterns that differentiate among the treatments tested.[22,32,33] Further, imaging studies demonstrate that medications and psychotherapy have differential effects on distinct brain regions,[23,34] suggesting that baseline activity may indicate response to one treatment vs the other. Although, to our knowledge, no prior imaging study has directly assessed the association of pretreatment brain activity patterns with differential response to different treatments (eg, medication vs psychotherapy), these past studies strongly suggest that a neuroimaging-based TSB can be defined.

In this study, we measured pretreatment brain glucose metabolism in patients with MDD randomized to receive a selective serotonin reuptake inhibitor (escitalopram oxalate) or cognitive behavior therapy (CBT).[35,36] Positron emission tomography (PET) scan measurement of glucose metabolism was selected based on its high reliability and availability combined with its established use for studies of baseline scan patterns in depression and effects of various antidepressant treatments.[22,23,28,34,37-43] Our aim was to define an imaging TSB for these 2 potential first-line treatments, ie, a brain activity pattern that distinguishes escitalopram remitters from both escitalopram nonresponders and CBT remitters while concurrently distinguishing CBT remitters from both CBT nonresponders and escitalopram remitters.

METHODS

PATIENT SELECTION

Written informed consent was obtained from all participants, with the protocol conducted as approved by the Emory institutional review board and registered at clinicaltrials.gov (NCT00367341). Eligible participants were adult outpatients with a primary diagnosis of MDD as assessed by the Structured Clinical Interview for *DSM-IV-TR* Axis I Disorders, Research Version, Patient Edition With Psychotic Screen[44] and confirmed through a psychiatric evaluation conducted by a study psychiatrist. Patients aged 18 to 60 years were recruited through the Mood and Anxiety Disorders Program at Emory University via advertisements and clinician referrals.[45] Patients were required to have moderate to severe symptoms of depression, defined as a 17-item Hamilton Depression Rating Scale (HDRS)[46] score of 18 or more at screening and 15 or more at the baseline randomization visit. Exclusion criteria included a current diagnosis of a primary psychiatric disorder other than MDD; a medical or neurological condition that could contribute to depression or that might interfere with response to treatment such as chronic pain syndromes and irritable bowel syndrome; current suicidal ideation requiring urgent clinical intervention; comorbid substance abuse within the past 3 months; substance dependence within 12 months prior to the screening visit; current or intended pregnancy or breastfeeding; use of antidepressants within 7 days of the screening visit (5 weeks for fluoxetine); current psychotherapy at the time of screening; or receipt of electroconvulsive therapy within 6 months of the screening visit. Patients were also excluded if they had a lifetime history of failure to respond to 6 or more weeks of treatment with escitalopram oxalate (≥10 mg/d) or 4 or more sessions of CBT for depression.

TREATMENT PROTOCOL

Treatment consisted of 2 phases: a short-term treatment phase (phase 1) and a combination treatment phase (phase 2). Phase 1 provided the data for this report. In phase 1, patients were randomly assigned (1:1 ratio) to receive a 12-week treatment course of either escitalopram oxalate (flexibly dosed from 10-20 mg/d) or manual-based, depression-focused CBT (16 one-hour sessions over 12 weeks) (**Figure 1**). Prior to study start, the study statistician prepared a permuted-block randomization schedule, with the assignments placed in order and sealed in opaque envelopes. Following acquisition of the pretreatment PET and magnetic resonance imaging scans, patients who continued to meet eligibility criteria were randomized to escitalopram or CBT. Escitalopram oxalate was started at 10 mg/d and could be increased to 20 mg/d at or after week 3 if the patient had an HDRS score more than 7 and was tolerating the medication. Down-titration to 10 mg/d was permitted if adverse effects were intolerable at the 20–mg/d dose. The CBT sessions were scheduled twice weekly for the first 4 weeks, followed by weekly sessions for the subsequent 8 weeks. Changes in symptom severity were assessed using the HDRS conducted by raters blinded to treatment group. Ratings were performed weekly for the first 6 weeks and then biweekly until week 12. Patients who did not remit on completion of their phase 1 treatment were offered enrollment in phase 2 comprising an additional 12 weeks of treatment with combination escitalopram and CBT.

OUTCOME METRICS

Clinical outcomes were defined using the HDRS, with the target end point being remission, defined as an HDRS score of 7 or less at both weeks 10 and 12 of phase 1 treatment,[47] to ensure stability of remission beyond a single "good week." Nonresponse was defined as a 30% or less HDRS score change from baseline to the phase 1 end point.[48] Partial responders (change in HDRS score >30% but not achieving remission) and dropouts were not included in the analyses for this report to avoid

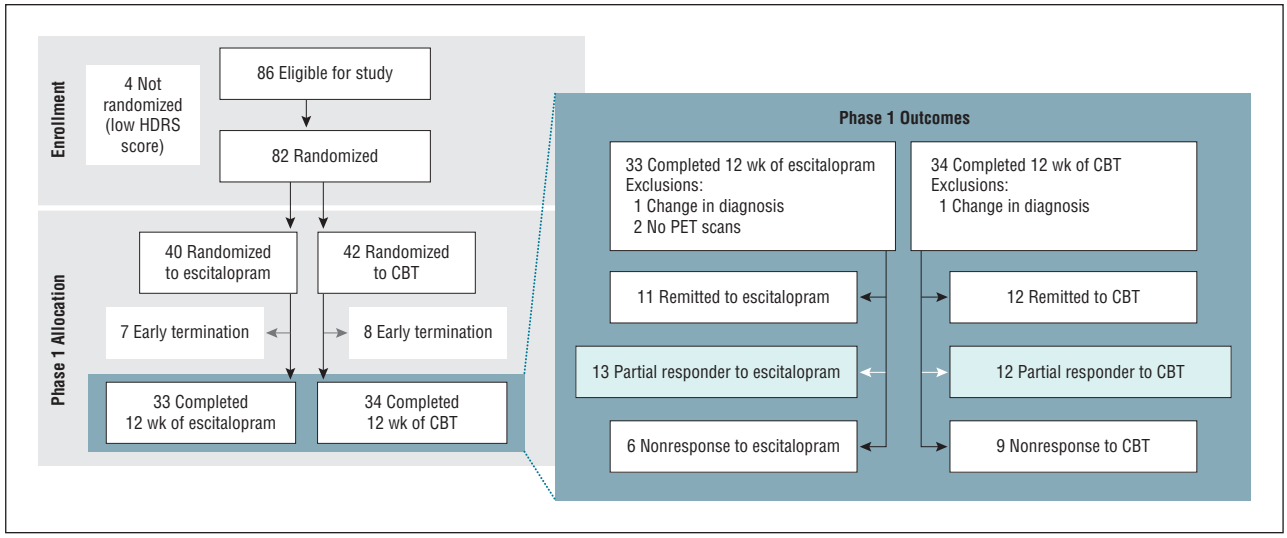

Figure 1. Study design and outcomes. Outcome groups defined by Hamilton Depression Rating Scale (HDRS) scores. Remission was defined as an HDRS score of 7 or less; partial response, as an HDRS score decrease of more than 30% but not achieving remission; and nonresponse, as an HDRS score decrease of 30% or less. Escitalopram was given as escitalopram oxalate. CBT indicates cognitive behavior therapy and PET, positron emission tomography.

potential dilution of either the remission or the nonresponse groups.

IMAGING ACQUISITION

Prior to treatment randomization, brain glucose metabolism was measured using PET (High-Resolution Research Tomograph scanner; Siemens), using standard methods without arterial blood sampling.[49] For each scan, a 370-MBq dose of fludeoxyglucose F18 (FDG) was administered intravenously, with a 20-minute 3-dimensional image acquisition beginning 40 minutes after tracer injection. During uptake, patients remained supine, awake, and resting with eyes closed and ears uncovered. Patients were given no explicit cognitive instructions but were asked to avoid ruminating on any 1 topic during the 40-minute FDG uptake period.[21] Raw emission images were corrected for injected dose and attenuation (using cesium 137, 6-minute transmission scan), reconstructed, and smoothed to an in-plane resolution of 4.0 mm Full-Width Half-Maximum.[34] A high-resolution T1-weighted structural magnetic resonance imaging scan was separately acquired for spatial normalization procedures and anatomical reference (TIM Trio 3-T whole-body scanner; Siemens) (3-dimensional magnetization-prepared rapid acquisition with gradient echo optimized at echo time = 5 milliseconds, repetition time = 35 milliseconds, matrix = $256 \times 208 \times 196$, and 1-mm isotropic resolution).

IMAGE PREPROCESSING

Attenuation-corrected PET images were coregistered to corresponding T1-weighted magnetic resonance imaging anatomical images using a 6-*df* linear transform and subsequently written into standard space using a nonlinear transform calculated from the T1-weighted image (DARTEL[50] and SPM8; Wellcome Trust Centre for Neuroimaging, http://www.fil.ion.ucl.ac.uk/spm/). Four patients had no anatomical scan and were normalized using a study-specific FDG template. Spatially normalized images were smoothed with an 8-mm Full-Width Half-Maximum Gaussian kernel and corrected for differences in whole-brain global mean activity.[23] Relative glucose metabolic rates were used for all analyses.

IMAGE ANALYSIS

A 2-way analysis of variance (ANOVA) with treatment (escitalopram or CBT) and outcome (remission or nonresponse) was performed to identify a putative escitalopram/CBT remission TSB using the baseline pretreatment FDG-PET scans (analyses performed with AFNI [National Institute of Mental Health, National Institutes of Health] and SPSS [IBM SPSS], statistical threshold $P < .001$ uncorrected, and a minimum cluster volume of 100 voxels, 0.34 mL). With this approach, a main effect of remission would identify brain regions associated with remission to treatment independent of randomization group, ie, a nonspecific biomarker. The treatment × outcome interaction would identify brain regions where the CBT treatment effect (remission or nonresponse) was distinguished from the escitalopram treatment effect (remission or nonresponse). Average normalized glucose metabolism values were extracted from clusters identified by the ANOVA (mean cluster activity) for further analysis.

Post hoc analyses of the extracted regions from the ANOVA interaction were used to refine selection of a potential TSB pattern by examining the effect sizes of the group differences for each region. We defined a region as a true TSB if it differentiated both the remission and nonresponse differences (by treatment) and the escitalopram and CBT differences (by outcome); thus, there were 4 comparisons of interest to consider when evaluating each region of interest as a stratification tool for treatment recommendation. Given the limited sample size, we report these comparisons using effect size, rather than statistical significance, to quantify their actual potential use as an eventual TSB. The 2-group effect size can be interpreted as the difference in metabolic activity between specified groups in units of standard deviation.[51] Because each region had a different magnitude of glucose metabolic activity and variation, each individual value was standardized using a *z* score, with regional *z* score means plotted to illustrate the nature of the regional interaction effects. Because these data are already standardized to the level of variation, there are no "error bars" in the related graphs.

To further assess the generalizability of findings identified in this restricted analysis to the full sample of study completers, metabolic activity was correlated with percentage of change in HDRS score within each treatment group to determine if the putative biomarkers identified in the ANOVA showed

the predicted general pattern in the full cohort of phase 1 treatment completers.

RESULTS

CLINICAL EFFECTS

Eighty-two patients were randomized to treatment; however, 2 patients received a change in their psychiatric diagnosis during the trial, and they were not used in the analyses. This resulted in 41 randomized to CBT and 39 to escitalopram. Sixty-five patients completed phase 1; 63 of the completers (79% of the total sample) had baseline FDG-PET scans available for analysis. Phase 1 remission rates were similar for both treatments: CBT = 12 of 33 (36.3%) and escitalopram = 12 of 30 (40.0%) (Figure 1 and **Table 1**). Nonresponse rates were also similar for both treatments: CBT = 9 of 33 (27.3%) and escitalopram = 6 of 30 (20.0%). Thirty-eight patients with clear outcomes and usable PET scans were included in the primary analysis: 12 patients with CBT remission, 11 patients with escitalopram remission, 9 patients with CBT nonresponse, and 6 patients with escitalopram nonresponse. There were no statistical differences in age, sex, or demographic or illness characteristics between randomization groups (escitalopram vs CBT). There were also no baseline demographic differences among the treatment-specific phase 1 outcome groups (Table 1). However, CBT nonresponders had higher baseline anxiety ratings (Hamilton Anxiety Rating Scale total score).

NEUROIMAGING RESULTS

Treatment × Outcome ANOVA

There was no significant main effect of remission, ie, no treatment-nonspecific biomarker was identified. Significant treatment × outcome interaction effects were demonstrated for 6 regions: right anterior insula, right inferior temporal cortex (Brodmann area [BA] 20), left amygdala, left premotor cortex (BA 6), right motor cortex (BA 4), and precuneus (BA 7) (**Table 2** and **Figure 2**).

Post hoc Analyses of Extracted Regions of Interest

The average effect sizes of each region for the various contrasts are shown in Table 2 in order of cluster size from the ANOVA. This was used to rank the regions of interest in the order of their potential utility as a discriminator. Only the insula and precuneus showed differences larger than 1 SD in all 4 contrasts, with the insula showing the largest average difference across all 4 comparisons. These findings indicate that metabolic activity of the right anterior insula is the most viable TSB candidate (Table 2 and **Figure 3**). Further, the anterior insula was the only region that showed relative hypometabolism in 1 group (region/whole-brain mean <1.0) and hypermetabolism in the other (region/whole-brain mean >1.0), adding support for potential use as a treatment stratification tool.

Assessment of the Insula TSB Across the Full Sample

There was a significant correlation between baseline insula activity and percentage of change in HDRS scores in both the CBT and escitalopram groups. A positive correlation was shown for the CBT group ($r = 0.55$; $df = 31$; $P = .001$) (Figure 3). In contrast, the escitalopram-treated patients showed an opposite but less significant correlation ($r = -0.31$; $df = 28$; $P = .09$). Both correlations are consistent with the more restricted findings in the binarized remitter-nonresponder analyses.

[a] Whole-brain 2-way analysis of variance with $P < .001$ uncorrected; voxel size, 1.5 mm × 1.5 mm × 1.5 mm.

[b] Effect size = mean difference divided by pooled standard deviation.

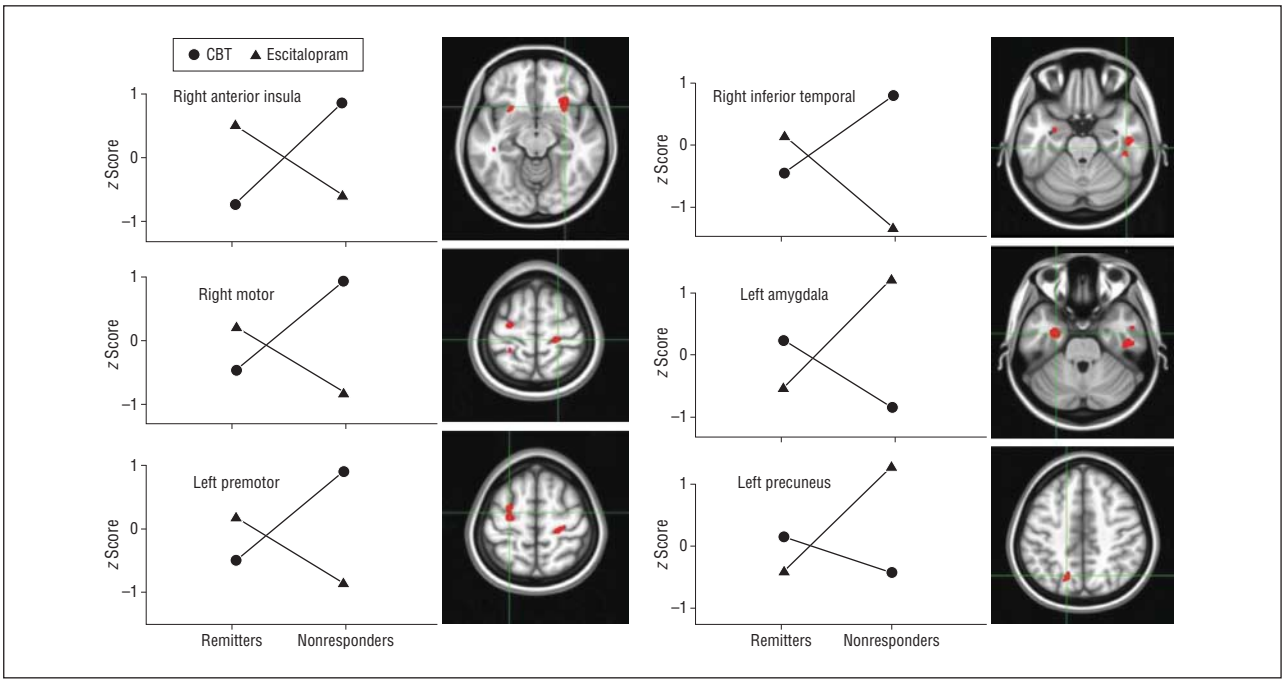

Figure 2. Potential treatment-specific biomarker candidates. Mean regional activity values for remitters and nonresponders segregated by treatment arm are plotted for the 6 regions showing a significant treatment × outcome analysis of variance interaction effect. Regional metabolic activity values are displayed as region/whole-brain metabolism converted to *z* scores. Regions match those shown in Table 2. Escitalopram was given as escitalopram oxalate. CBT indicates cognitive behavior therapy.

Although not a primary planned analysis, the presence of multiple regions identified in the ANOVA suggests that a combination rather than a single TSB might be more accurate in discriminating the groups. Although underpowered, a principal component analysis was performed using the 6 identified regions of interest. All regions loaded on 1 factor, which did not provide superior internal consistency to the insula alone (data not shown).

DISCUSSION

This 12-week randomized study of 2 first-line treatments for MDD identified 2 FDG-PET–defined brain pattern subtypes that differentially predicted remission to either CBT or escitalopram. Among the 6 identified cortical and limbic regions, the anterior insula metabolism best discriminated treatment outcome: insula hypometabolism was associated with remission to CBT and poor response to escitalopram, while insula hypermetabolism was associated with remission to escitalopram and poor response to CBT. These data suggest that insula metabolism alone (relative to each person's whole-brain mean metabolism) may serve as a pretreatment biomarker to guide initial treatment selection (medication vs CBT) for a patient presenting with a major depressive episode. To validate the insula TSB, a prospective replication study in which patients are treated according to brain type will be required. That said, this forced-choice analytic strategy establishes a potential stratification algorithm for man-

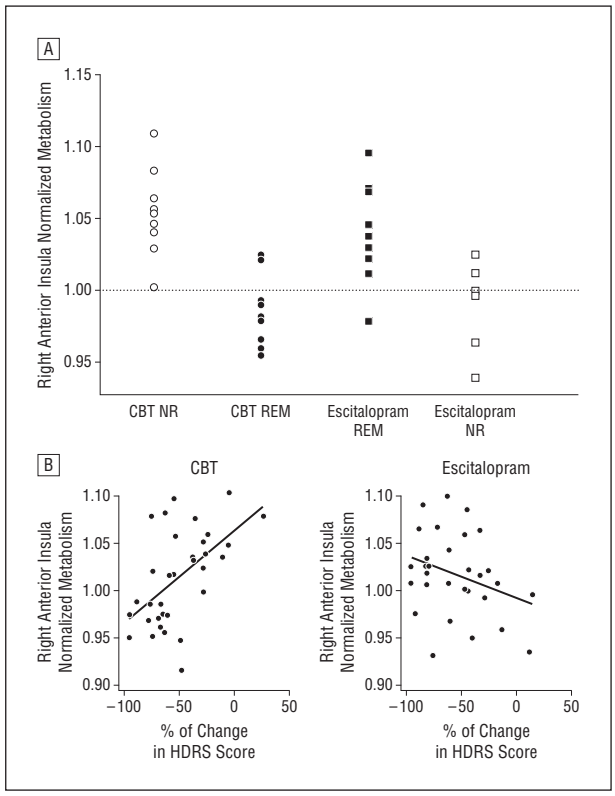

Figure 3. Right anterior insula as the optimal treatment-specific biomarker candidate. Expanded view of findings. A, Scatterplot of insular activity from individual subjects in the remitter (REM) and nonresponder (NR) groups. Note: the anterior insula is the only region where the interaction subdivides patients into hypermetabolic (region/whole-brain mean >1.0) and hypometabolic (region/whole-brain mean <1.0) subgroups. B, Correlations of insula activity with percentage of change in Hamilton Depression Rating Scale (HDRS) score in the full cohort of subjects treated with cognitive behavior therapy (CBT) and escitalopram oxalate.

aging patients with MDD based on brain state rather than patient or professional preference, anticipating the real-world decision-making process faced by clinicians, namely, choosing a first treatment that will most likely lead to remission while also avoiding a treatment that is likely to fail.

A role for the anterior insula in major depression is well established. The insula is crucial in mediating the translation of visceral experiences to subjective feeling states.[52] Additionally, anterior insula activity is linked to behaviors relevant to depression including interoception, emotional self-awareness, decision making, and cognitive control.[53-55] The anterior insula is extensively connected to various frontal, limbic, and brainstem regions, including the anterior cingulate cortex, amygdala, and hypothalamus.[56] Volume reductions of the anterior but not posterior insula have been described in currently ill patients with MDD as well as patients with remitted MDD compared with healthy controls.[57] Changes in insula activity occur with a variety of treatments for MDD, including medication,[58] vagus nerve stimulation,[59] deep brain stimulation,[60] and mindfulness training,[61] suggesting a role for this region in mediating antidepressant response and remission more generally.[62] Notably, past studies have reported both increases[33] and decreases[39] in baseline resting-state activity relative to never-depressed control subjects. This is consistent with the presence of at least 2 baseline patterns within the broader population of depressed patients. Most recently, baseline insula activity has been correlated with response to vagus nerve stimulation.[26] These previous studies taken together with the current findings support the anterior insula as a potential candidate for an imaging TSB.

Contrary to past published studies,[63] the rostral anterior cingulate did not discriminate the outcome subgroups in either the main effect or interaction analyses. A post hoc examination of responder and nonresponder differences within each treatment arm did reveal a nonsignificant rostral cingulate activity difference, with metabolism in responders greater than nonresponders, but solely in the escitalopram group. While consistent with past reports, this finding did not meet the TSB criteria defined for the current study, ie, a region whose activity can differentiate both good and poor outcomes for both treatments.

Critical to the stated aims, remission (rather than response) was the targeted end point in this study because the presence of residual symptoms is a known predictor of clinical relapse, even in patients with significant improvement.[64,65] Because the primary aim of this study was to identify distinct brain patterns that optimally predict remission to each of 2 specific treatments, patients with unclear treatment outcomes were excluded from the primary analysis (ie, responders without remission and partial responders). This enriched sample allowed for detection of clear remission and nonresponse signals; as such, these analyses did not attempt to characterize the neurobiological variability of patients with more ambiguous clinical outcomes. This is a commonly used approach when the goal is to develop or test a biological signal for stratifying subjects.[66,67] Nevertheless, baseline insula activity did correlate significantly with change in depression severity across all subjects, supporting the interpretation that insula activity is a plausible TSB suitable for further testing. Based on the correlational analysis across all subjects, the data further suggest that the anterior insula TSB may most optimally identify those patients who require CBT.

If confirmed with prospective testing, this putative TSB has both clinical and pathophysiological implications. At present, treatment failure with antidepressant medication often leads to the addition of a second drug and not a categorical switch to an evidence-based psychotherapy.[68] Results herein suggest that patients who require CBT have a distinct neurophysiology that differs categorically from patients who require escitalopram and knowledge of such may help to improve current clinical practice patterns. Further, using this or any other imaging-based TSB to define patient subgroups provides a brain-based platform to investigate genetic, immune, neuroendocrine, and behavioral variations from a new perspective.

While these first results are encouraging, there are several limitations. Clearly, there are patients who are not successfully treated with either of these 2 options, either alone or in combination.[69] Therefore, our strategy can be best seen as a first-line stratification approach to treat-

Downloaded From: http://archpsyc.jamanetwork.com/ by a Universita Torino User on 06/14/2013

ment selection. Future studies, in addition to testing this insula biomarker prospectively, should include a design that works to identify patients resistant to both of these first-line treatments.[60,70]

The lack of a placebo arm could be considered a limitation, but given the randomized design of the study, there is no reason to believe that placebo responders would be unevenly distributed between the 2 groups. Thus, even if present, placebo effects on remission rates would be expected to be similar in both treatment groups. Although inclusion of a placebo arm might have provided further insights into mediators of improvement during treatment, the absence of a placebo arm does not diminish the potential clinical utility of the identified TSB.

It is also possible that these results are specific to the cohort recruited for this trial. As such, a stratification strategy based on insula metabolism will require prospective testing in a new group of comparably depressed patients. Similarly, additional studies will be required to determine if remitters to other medications have a similar or different TSB from that seen with escitalopram or if remitters to other evidence-based psychotherapies have a similar TSB to that seen with CBT.[71,72] Such studies are critical next steps toward the development of biology-based algorithms to guide treatment selection for MDD at all stages of illness. Still, if replicated, the insula TSB defined in this study would provide the first objective marker to guide initial treatment selection for major depression, an important advance in potentially reducing the costs and disability associated with this highly prevalent disorder.

Conflict of Interest Disclosures: Dr Dunlop has received honoraria for consulting work performed for Bristol-Myers Squibb, MedAvante, Pfizer, and Roche. He has received research support from AstraZeneca, Bristol-Myers Squibb, Evotec, Forest, GlaxoSmithKline, Novartis, Ono Pharmaceuticals, Pfizer, Shire, Takeda, and Transcept. Dr Holtzheimer has received consulting fees from St Jude Medical Neuromodulation and Cervel Neurotech and an honorarium from Johnson & Johnson. Dr Craighead is a board member of Hugarheill, an Icelandic company dedicated to the prevention of depression, and he receives book royalties from John Wiley & Sons. He is a consultant to the George West Mental Health Foundation that oversees Skyland Trail, a residential treatment facility in Atlanta, Georgia. Dr Mayberg has received consulting and intellectual property licensing fees from St Jude Medical Inc.
Funding/Support: This work was supported by National Institutes of Health grants R01 MH073719 (Dr Mayberg), T32 GM08695 (Ms McGrath), K23 MH086690 (Dr Dunlop), and K23 MH077869 (Dr Holtzheimer).
Additional Contributions: Treating psychotherapists: Sheethal Reddy, PhD, Patrick Sylvers, PhD, Lorie Ritschel, PhD, Meredith Jones, PhD, Mary Heekin, LCSW, Maryrose Gerardi, PhD, and Jill Rosenberg, LCSW. Treating physicians: Ebrahim Haroon, MD, Jeffrey Rakofsky, MD, Dylan Wint, MD, and Corey Beck, MD. Clinical coordinators: Ronald Chismar, RN, Melanie Galanti, BA, Rachelle Gibson, RN, Lauren Marx, BS, Melissa McKenzie, BA, and Tanja Mletzko, MA. Imaging team: Rebecca DeMayo, MA, Eundria Hill, MSW, Kiseung Choi, MS, and Justin Rajendra, BA. Raters: Margo Aaron, BA, Yara Betancourt, BA, Cristina Velasquez Delgado, BA, Novall Khan, BS, Ximena Marincic, BS, and Christopher Vaughan, BA.

Summary

Treatment-resistant depression is a severely disabling disorder with no proven treatment options once multiple medications, psychotherapy, and electroconvulsive therapy have failed. Based on our preliminary observation that the subgenual cingulate region (Brodmann area 25) is metabolically overactive in treatment-resistant depression, we studied whether the application of chronic deep brain stimulation to modulate BA25 could reduce this elevated activity and produce clinical benefit in six patients with refractory depression. Chronic stimulation of white matter tracts adjacent to the subgenual cingulate gyrus was associated with a striking and sustained remission of depression in four of six patients. Antidepressant effects were associated with a marked reduction in local cerebral blood flow as well as changes in downstream limbic and cortical sites, measured using positron emission tomography. These results suggest that disrupting focal pathological activity in limbic-cortical circuits using electrical stimulation of the subgenual cingulate white matter can effectively reverse symptoms in otherwise treatment-resistant depression.

Introduction

Major depression is the most common of all psychiatric disorders (Wang, 2003). It ranks among the top causes of worldwide disease burden and is the leading source of disability in adults in North America under the age of 50 (World Health Organization, 2001). While depression can be effectively treated in the majority of patients by either medication or some form of evidence-based psychotherapy (American Psychiatric Association, 2000), up to 20% of patients fail to respond to standard interventions (Fava, 2003; Keller et al., 1992). For these patients, trial-and-error combinations of multiple medications and electroconvulsive therapy are often required (Kennedy and Lam, 2003; Lancet UK ECT Review Group, 2003; Sackeim et al., 2001). For patients who remain severely depressed despite these aggressive approaches, new strategies are needed. We describe a strategy directed at this group of treatment-refractory patients with major depression.

Converging clinical, biochemical, neuroimaging, and postmortem evidence suggests that depression is unlikely to be a disease of a single brain region or neurotransmitter system. Rather, it is now generally viewed as a systems-level disorder affecting integrated pathways linking select cortical, subcortical, and limbic sites and their related neurotransmitter and molecular mediators (Manji et al., 2001; Mayberg, 1997; Nemeroff 2002; Nestler et al., 2002; Vaidya and Duman, 2001). While mechanisms driving this "system dysfunction" are not yet characterized, they are likely to be multifactorial, with genetic vulnerability, developmental insults, and environmental stressors all considered important and synergistic contributors (Caspi et al., 2003; Heim et al., 2000; Kendler et al., 2001). Treatments for depression can be similarly viewed within this limbic-cortical system framework, where different modes of treatment modulate specific regional targets, resulting in a variety of complementary, adaptive chemical and molecular changes that re-establish a normal mood state (Vaidya and Duman 2001; Hyman and Nestler, 1996, Mayberg 2003).

Functional neuroimaging studies have had a critical role in characterizing these limbic-cortical pathways (Brody, et al., 2001; Drevets, 1999; Mayberg, 1994, 2003). Our own studies have demonstrated consistent involvement of the subgenual cingulate (Cg25) in both acute sadness and antidepressant treatment effects, suggesting a critical role for this region in modulating negative mood states (Mayberg et al., 1999; Seminowicz et al., 2004). In support of this hypothesis, a decrease in Cg25 activity is reported with clinical response to different antidepressant treatments including specific serotonin reuptake inhibitor (SSRI) antidepressant medications, electroconvulsive therapy (ECT), re-

petitive transcranial magnetic stimulation (rTMS), and ablative surgery (Dougherty et al., 2003; Goldapple et al., 2004; Malizia, 1997; Mayberg et al., 2000; Mottaghy et al., 2002; Nobler et al., 2001).

In addition, Cg25 connections to the brainstem, hypothalamus, and insula have been implicated in the disturbances of circadian regulation associated with depression (sleep, appetite, libido, neuroendocrine changes) (Barbas et al., 2003; Freedman et al., 2000; Jurgens and Muller-Preuss, 1977; Maclean, 1990; Ongur et al., 1998). Reciprocal pathways linking Cg25 to orbitofrontal, medial prefrontal, and various parts of the anterior and posterior cingulate cortices form the neuroanatomical substrates by which primary autonomic and homeostatic processes influence various aspects of learning, memory, motivation and reward—core behaviors altered in depressed patients (Barbas et al., 2003; Carmichael and Price, 1996; Haber, 2003; Vogt and Pandya, 1987).

Recent advances in the surgical treatment of Parkinson's disease have demonstrated that chronic high-frequency deep brain stimulation (DBS) in pathologically overactive brain circuits produces profound clinical benefits (Benabid, 2003; Lang and Lozano, 1998). We have previously shown that clinically effective DBS in the basal ganglia produces both local and remote changes in neural activity as assessed by positron emission tomography (PET) (Davis et al., 1997). We have now leveraged these observations to investigate whether DBS could be used to modulate pathological brain circuits in depression.

We tested the hypothesis that the use of chronic stimulation to modulate Cg25 gray matter and interconnected frontal and subcortical regions could reverse the pathological metabolic activity in these circuits and produce clinical benefits in patients with treatment-resistant depression (TRD). This study reports the use of high-frequency subgenual cingulate white matter (Cg25WM) DBS in six TRD patients.

Results

Patients

All six patients met DSM IV-TR criteria for major depressive disorder (MDD) with a major depressive episode (MDE) of at least 1 year duration diagnosed by structured clinical interview for DSM IV-TR (First et al., 2001), and all had severe depression with a minimum score at entry of 20 on the 17 item Hamilton Depression Rating Scale (HDRS) (Hamilton, 1960). Each met stringent criteria for treatment resistance defined as failure to response to a minimum of four different antidepressant treatments, including medications, evidence-based psychotherapy, or electroconvulsive therapy, administered at adequate doses and duration during the current episode (Fava, 2003; Sackeim et al., 2001; Thase and Rush 1997). Subjects' demographic characteristics are presented in Table 1.

Intraoperative Findings

DBS electrodes were implanted in Cg25WM under local anesthesia using MR imaging guidance (Figure 1, row 1: A/B and row 2: C/D) (Schaltenbrand and Wahren, 1977). A protocol similar to that used in evaluating stimulation thresholds for efficacy or adverse effects in patients with Parkinson's disease was adopted for use in these patients (Benabid, 2003; Davis et al., 1997; Lang and Lozano, 1998). The spontaneous report or occurrence of any acute behavioral, cognitive, motor, or autonomic effects was sought during blinded, sequential stimulation of successive, individual contacts (monopolar stimulation, 60 μs pulsewidths, 130 Hz). Voltage was progressively increased up to 9.0 V at each of the eight electrode contacts (four per side), as tolerated. Voltage was increased by approximately 1.0 V every 30 s, with a 15–20 s pause between adjustments, allowing time for patients to identify an effect, if present. Patients reported no motor or sensory phenomena that cued them as to whether current was either on or off.

All patients spontaneously reported acute effects including "sudden calmness or lightness," "disappearance of the void," sense of heightened awareness, increased interest, "connectedness," and sudden brightening of the room, including a description of the sharpening of visual details and intensification of colors in response to electrical stimulation. Reproducible and reversible changes in these phenomena, time locked with stimulation, were observed at specific contacts and parameters for individual patients and not with sham or subthreshold stimulation at those same sites. Increases in motor speed, volume, and rate of spontaneous speech and improved prosody were observed. In addition, changes in both positive and negative affective rating scores (PANAS scale) (Watson and Clark, 1988) occurred coincident with the patients' spontaneous statements. There were no overt adverse affective or autonomic changes with stimulation at settings producing these improvements. However, all patients experienced stimulation dose-dependent adverse effects including lightheadedness and psychomotor slowing at high settings (over 7.0 Volts), most often seen at the superior electrode contact.

Postoperative Findings: Short-Term Stimulation Effects

Postoperative MR imaging confirmed the placement of the DBS electrodes within the subgenual cingulate white matter (Cg25WM) bilaterally as targeted. (Figure 1, row 3: E/F). During the 5 day postoperative period, and prior to placement of the pulse generator, daily short sessions of DBS were used to refine final contact selection and stimulation parameters. Systematic testing of individual and paired unilateral and bilateral contacts was performed with a variety of parameters (monopolar [contact anode; case cathode] and bipolar, pulsewidth of 30–250 μs, frequency of 10–130 Hz, progressive increase in voltage from 0.0–9.0 Volts). Acute behavioral changes were again observed during these test sessions. Reproducible improvements in interest, motor speed, activity level, and PANAS scores (reduced negative, increased positive scores) were seen during these stimulation sessions generally using the same contacts and parameters that induced effects in the operating room.

To control for the possibility of a placebo effect, patients were blinded as to which contact was being stim-

ulated and to the parameter settings. Sham stimulation using either 0.0 Volts or subthreshold stimulation failed to elicit any changes in behavior. Randomized, acute *off-on-off-on* trials of varying short periods of stimulation (1–5 min) at optimal settings produced consistent stimulation-locked behavioral improvements. Unexpectedly, with application of stimulation for progressively longer periods (from 1 to 3 hr), there was an increasing and correspondingly longer carry-over of the beneficial behavioral effects beyond cessation of the stimulation. These longer stimulation periods were free of adverse effects and were the basis for selecting the stimulation settings used chronically.

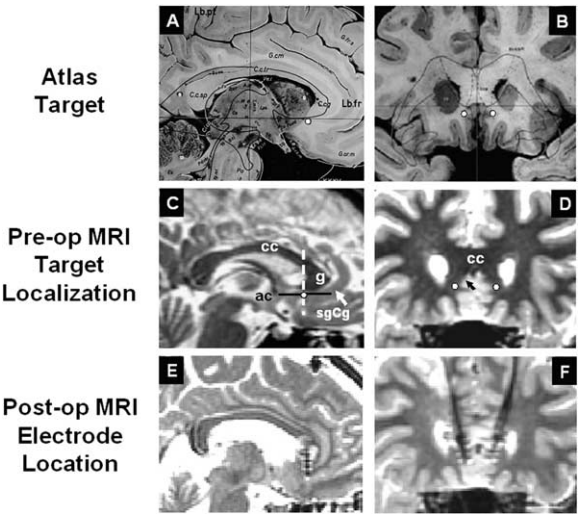

Figure 1. DBS Electrode Placement in the Subgenual Cingulate White Matter

(Row 1) Sagittal (left, [A]) and coronal (right, [B]) views of the subgenual cingulate target (white circles) localized on the Schaltenbrandt neurosurgical atlas. (Row 2) Sagittal (C) and coronal (D) views of the DBS target mapped on a high-resolution T1 MRI scans for one patient. (Row 3) Sagittal (E) and coronal (F) views of postop MRI scans demonstrating the location of electrodes for a single subject with the ventral contact centered within the predetermined location. sgCg, subgenual cingulate; cc, corpus callosum; g, genu of the corpus callosum; ac, anterior commissure; white circles, electrode target in sgCg white matter; white and black arrows, sgCg gyrus; dotted line, anterior-posterior position of the electrode relative to the ac-g line.

Postoperative Selection of Stimulation Parameters

Patients were discharged home with stimulation "off" following implantation of the pulse generators. One week later, chronic DBS was initiated using the lowest voltage and specific electrode contacts that had previously produced acute behavioral effects. Parameters of stimulation were reassessed at weekly intervals with minor adjustments in voltage made to optimize clinical effects. Following a 4 week period of parameter optimization, settings generally remained stable for the remainder of the 6 month follow-up period. The mean stimulation parameters used in this group at 6 months were 4.0 Volts, 60 μs pulsewidths, at a frequency of 130 Hz.

Efficacy of Chronic Bilateral Cg25WM DBS

Standard criteria for antidepressant response and remission were applied (Frank et al., 1991). Response was defined as a decrease in the HDRS-17 score of 50% or greater from the pretreatment baseline; remission as an absolute HDRS-17 score <8. One month postop, two patients met criteria for clinical response (Table 2). By 2 months, five of the six patients met the defined response threshold. Continued antidepressant response was seen in four of these subjects, with some variability up to 5 months. At the 6 month study endpoint, antidepressant response was maintained in four subjects (66%). Moreover, three of these subjects achieved remission or near remission of illness. Consistent with the improvements seen in the HDRS-17 scores, comparable changes were also demonstrated on other quantitative depression scales (see Table 3). Presurgical medications and doses were unchanged throughout the 6 month study.

Normalization of early-morning sleep disturbance (middle insomnia commonly seen in MDD) occurred in the first week of chronic DBS in four of the six subjects (patients 1, 3, 5, and 6) and was the first notable sus-

tained symptom change. Over the initial few weeks of continuous DBS, increased energy, interest, and psychomotor speed were additionally reported, with effects generally appreciable a day or two following stimulation adjustments. Patients and their families described renewed interest and pleasure in social and family activities, decreased apathy and anhedonia, as well as an improved ability to plan, initiate, and complete tasks that were reported as impossible to attempt prior to surgery. While all patients continued to report feeling "moderately depressed" for several weeks, several also indicated that the sensations of "painful emptiness" and "void" remitted almost immediately following onset of stimulation at the optimal contacts.

Two patients failed to show a sustained antidepressant response at the 6 month time point (Table 2). One of these subjects, patient 2, met criteria for clinical response in the first 4 months; however, the level of improvement fluctuated over time, and the maximal benefit could not be recaptured with either a change in the stimulation contact or adjustments in stimulation parameters after 4 months. Patient 4 had no appreciable clinical improvement with chronic stimulation despite trials with various combinations of contacts and stimulation parameters. Of note, the prominent sleep disturbances in these two patients (difficulty falling asleep [patient 4] and hypersomnia [patient 2]) were not affected by DBS, unlike the middle insomnia improvements seen in the other four subjects.

Control Condition: Blinded DBS Discontinuation

We next considered that the long-term benefit in the responders could be related to placebo or nonspecific factors. To examine this possibility, after a period of continuous stimulation for 6 months, the effects of cessation and reintroduction of stimulation was examined in patient 1, who had shown the earliest, most robust, and best-sustained clinical response (Table 2). Following blinded discontinuation of bilateral stimulation (stimulators set at 0.0 V), antidepressant effects were maintained for 2 weeks (HDRS = 9; PANAS positive score = 48 of out of a possible 50, PANAS negative score = 10 out of a possible 50 versus 6 month score positive = 50, negative = 10). In weeks 3 and 4 without stimulation, the improvements in mood were also sustained (HDRS = 10). In the context of this sustained euthymia, however, there was a progressive change in behavior characterized by loss of energy and initiative, impaired concentration, and reduced activities, reflected by a drop in the PANAS positive score to 37, without appreciable change in the negative score (negative = 13). At this point, and under continued blinded conditions, the stimulator was turned back on to the previous best settings (3.5 V, PW 60, 130 Hz). This resulted in normalization of symptoms within approximately 48 hr and return to prediscontinuation activities within 1 week (HDRS = 6, PANAS positive = 50, negative = 10 after 1 week of restarting chronic DBS). This remission was sustained at 6 weeks of resu-

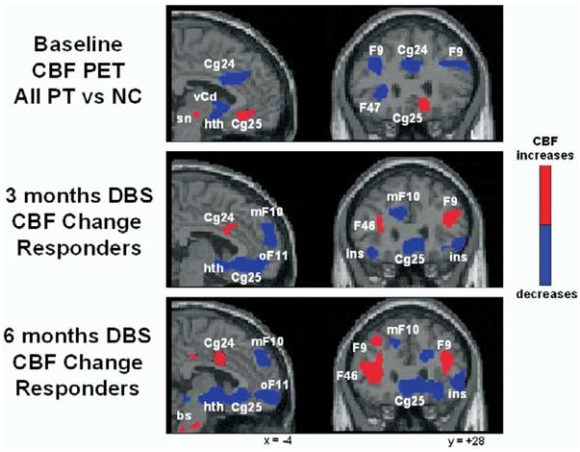

Figure 2. PET Scans

Regional cerebral blood flow changes (CBF PET) in TRD patients at baseline (row 1) and after 3 months (row 2) and 6 months (row 3) of successful treatment with continuous DBS. Sagittal (left) and coronal (right) views. Baseline CBF abnormalities are seen relative to age- and gender-matched healthy control subjects (NC): increases in subgenual cingulate (Cg25) and decrease in dorsolateral prefrontal (F9), ventrolateral prefrontal (F47) and anterior cingulate (Cg24) cortices (row 1, patients 1–5). Three months of DBS relative to baseline (row 2, patients 1, 3, and 5): decreases in Cg25, hypothalamus (Hth), anterior insula (ins), medial frontal (mF10) and orbital frontal (oF11); increases in prefrontal (F9/46) and dorsal cingulate (cg24). This same pattern is maintained at 6 months, although additional increases are seen in the brainstem (bs) (row 3). Slice location is in millimeters relative to anterior commissure. Numbers are Brodmann designations. L, left. Significant CBF increases in red; decreases in blue ($p < 0.001$).

med stimulation at comparable levels to the prediscontinuation baseline (HDRS = 4). Taken together, these findings suggest that stimulation of Cg25WM produces long-term improvements in mood that are sustained beyond the period of active stimulation. The cognitive aspects of depression (i.e., poor concentration, apathy) also show sustained improvements, but the observed changes appear to have a different biology and kinetics, decaying closer to the cessation of stimulation.

PET Measures of Regional Blood Flow: Baseline and Treatment Effects

Positron emission tomography was used to characterize the activity in brain networks involved in TRD and to provide a quantitative measure of brain changes associated with stimulation. Baseline, resting-state, cerebral blood flow (CBF) PET scans were performed in the first five study subjects and compared to five age- and sex-matched, nondepressed healthy volunteers. Depressed patients showed a unique pattern of elevated subgenual cingulate (Cg25) blood flow at pretreatment baseline, not previously reported in studies of nontreatment resistant patients. In addition, and consistent with past studies of depressed patients (reviewed in Mayberg, 2003), CBF decreases in prefrontal (BA9/46), premotor (BA6), dorsal anterior cingulate (BA24), and anterior insula were also identified (Figure 2 row 1; Table 4, left). A similar pattern of hyperactive Cg25 and hypoactive prefrontal cortex was seen in both the DBS responders and nonresponders (data not shown). Responder versus nonresponder differences at baseline were seen primarily in the magnitude of the prefrontal decreases (responders > nonresponders). Responders also showed an area of hyperactivity in the medial frontal cortex (BA10) not seen in the nonresponders; however, the small sample size precluded further analysis.

The time course of CBF changes with chronic stimulation of Cg25WM was also examined to establish the relationship of regional brain functioning to behavioral effects. Serial scans were performed after 3 and 6 months in four of the first five patients (1, 2, 3, and 5). Group analyses showed local CBF decreases in Cg25 and adjacent orbital frontal cortex (BA11) after 3 months of stimulation. The long-term responders (patients 1, 3, and 5) showed additional CBF changes at both 3 and 6 months: decreases in hypothalamus, anterior insula, and medial frontal cortex (BA10) as well as increases in dorsolateral prefrontal (BA9/46), dorsal anterior (BA24) and posterior cingulate (BA31), premotor (BA6), and parietal (BA40) regions (Table 4; Figure 2, rows 2 and 3). Neither the medial frontal (BA10) decreases nor the dorsal prefrontal (BA9/46), anterior cingulate (BA24), or parietal (BA40) increases were seen in the nonresponder (patient 2) at either 3 or 6 months (data not shown).

The stimulation-induced CBF increases in prefrontal cortex (BA9/46) normalized pretreatment abnormalities. Similarly, the Cg25 decreases not only normalized pretreatment dysfunction, but activity in this region with DBS was actually suppressed below that of the controls at both time points, a change also observed in our previous studies of PET scan changes with response to antidepressant medications (Mayberg et al., 2000). Unlike medication, brainstem changes were not seen early with DBS, although changes in the pons were demonstrated at the 6 month time point. Overall, regional changes seen after 3 months were maintained at 6 months in all three responders (Table 4, middle and right sections).

Neuropsychological Testing

A comprehensive neuropsychological battery was performed prior to surgery and after 3 and 6 months of stimulation, coincident with the day of the PET scan sessions. The test battery was designed to differentiate dorsolateral, superior medial, and ventrolateral/orbital frontal behaviors, potentially affected by chronic Cg25WM DBS. Serial testing further allowed differentiation between subacute surgical effects, chronic stimulation effects, and correlations with mood change.

At baseline, all patients were functioning intellectually in the average range, consistent with estimates of premorbid IQ. Inspection of results over time indicates that surgery itself did not have a negative impact on general cognition (i.e., IQ, language, basic visual-spatial function). Moreover, many specific areas that were below average or impaired at baseline were significantly improved (or trending due to low power) following 6 months of DBS [responders: visuo-motor function, particularly with the nondominant hand, $t(2) = 5.8$,

[a] Patients 1–5 versus five age- and gender-matched healthy controls.
[b] Patients 1, 3, and 5.
[c] SPM t maps. Significance threshold: $p < 0.001$ uncorrected ($t > 3.27$); cluster size >50 voxels.

p = 0.014; dorsolateral frontal function (verbal fluency), t(2) = 10.0, p = 0.005; ventral prefrontal function (fewer errors on object alternation task), t(2) = 1.7, p = 0.12; and orbital frontal function (fewer risky choices on the gambling task), t(2) = 6.3, p = 0.012]. Importantly, there were no acquired impairments in orbital frontal functioning to indicate local DBS adverse effects (Kartsounis et al., 1991; Dalgleish et al., 2004). Nonresponders had normal performance on all tests at baseline, with the exception of slowed psychomotor speed (consistent with effects of depression). Repeat testing was only available for one of these subjects.

Adverse Events

Patients 2 and 4 developed local infections related to the connector cable at the chest (patient 2) or scalp (patient 4). Both were treated with intravenous antibiotics. Because of persistent infection in the absence of clinical benefit, the devices were explanted at approximately 6 months with resolution of their infections. No worsening of depressive symptoms was observed in either subject following explantation. Patient 5 developed skin erosion over the hardware and also received antibiotics. While no definitive etiology of these infections was identified, the protocol was modified after patient 5 to implant both the electrodes and pulse generator in a single surgical session, thus eliminating the several-day period where the electrodes remained externalized.

Discussion

In this study, we have demonstrated that high-frequency DBS of the Cg25WM can produce striking behavioral changes in patients with TRD. Acute behavioral effects were time locked to stimulation intraoperatively and during short-term testing sessions. Furthermore, sustained clinical improvements decreased with blinded discontinuation of chronic DBS and were recaptured with reinstitution of stimulation, providing evidence as to the specificity of DBS-mediated changes. PET scan data further indicate that Cg25WM DBS has profound effects on the cerebral networks involved in depression and suggest that reversal of baseline abnormalities correlates with antidepressant benefits. While the number of subjects is small, four of six patients (66%) achieved sustained clinical response or remission at the end of 6 months without changes in concurrent medications. This response rate is striking given the extreme treatment refractoriness of this patient population and the well-documented low and poorly sustained placebo response rates of such pa-

tients (Fava, 2003; Keller, et al., 1992; Kennedy and Lam, 2003; Thase and Rush, 1997; Sackeim et al., 2001).

The identified CBF change pattern associated with DBS-induced antidepressant effects has important similarities to other therapies for depression. The pattern of reduced activity in the Cg25 and hypothalamus together with prefrontal (BA9) and brainstem increases during DBS are identical to changes reported with antidepressant response to medication (Mayberg et al., 2000). On the other hand, the medial frontal (BA10)/orbital frontal (BA11) decreases and dorsal cingulate (BA24) increases are similar to the change pattern observed with response to cognitive behavioral therapy (Goldapple et al., 2004). The observation that the changes with DBS seen here features both the antidepressant medication and the CBT- induced changes suggests that Cg25WM DBS acts at a critical node of a distributed mood-regulatory network involved in major depression (Mayberg, 2003; Seminowicz et al., 2004).

The baseline pattern of subgenual cingulate hyperactivity in combination with frontal hypoactivity described here in this TRD patient group is a finding that is in contrast to the hypoactivity reported in a more rostral region of subgenual medial prefrontal cortex in familial bipolar and unipolar depressed patients (Drevets et al., 1997). This distinction suggests important differences across subtypes of depression that are potentially relevant to the pathophysiology of major depressive disorders and perhaps their treatment.

Although the mechanisms of action of DBS are incompletely understood, it is clear that stimulation produces both local and remote regional effects (Davis et al. 1997). The behavioral and neuroimaging changes in this study are consistent with suppression of the abnormally elevated baseline Cg25 activity (Figure 2). Possible mechanisms include DBS-induced activation of inhibitory GABA-ergic afferents and/or high frequency stimulation induced synaptic or metabolic failure (Gabbott et al., 1997; Lozano et al., 2002; McIntyre et al., 2004). The remote cortical and brainstem increases could occur as an indirect consequence of *trans*-synaptic effects in response to decreased activity in Cg25, or direct anterograde or retrograde activation of WM projections coursing through the stimulation field (Barbas et al., 2003; Carmichael and Price, 1996; Haber, 2003; Freedman et al., 2000; Ongur et al., 1998; Jurgens and Muller-Preuss, 1977; Vogt and Pandya, 1987).

In context of these putative mechanisms, the sudden mood change seen with stimulation in the operating room is consistent with an acute deactivation of a hyperactive Cg25, the region immediately adjacent to the area of stimulation. This region has been previously shown to mediate negative mood (increases with sadness, decreases with alleviation of depressive dysphoria) (Mayberg et al., 1999). Early effects of DBS on sleep, energy and motivation also suggest changes in activity of the hypothalamus and brainstem, regions monosynaptically connected to Cg25 (Barbas et al. 2003; Freedman et al., 2000; Jurgens and Muller-Preuss, 1977; Ongur et al., 1998). The more global changes in functioning, i.e., resolution of the depressive syndrome, as well as the prolonged washout time and associated persistent benefit we have observed beyond the cessation of stimulation, may reflect long-term changes in neural network properties as a consequence of prolonged stimulation (Carmichael and Price, 1996; Vaidya and Duman, 2001; Haber, 2003; Vogt and Pandya, 1987). This phenomenon of ongoing benefit after DBS discontinuation has been observed in other disorders targeting different brain circuits, including epilepsy, essential tremor, dystonia, and Parkinson's disease (Hodaie et al. 2002, Kumar et al. 2003; Deep-Brain Stimulation for Parkinson's Disease Study Group, 2001; Vidailhet et al., 2005).

Despite these encouraging results, there are limitations to this first study of Cg25WM DBS for TRD. Sample size was small, follow-up was limited, and no sham surgery or systematic placebo control arm was used. There was also inadequate power to identify demographic, clinical, subtype, neuropsychological, or imaging markers that might predict response. It may be relevant that all four responders had their first major depressive episode (MDE) before age 35 and had predominant melancholic features whereas the two nonresponders had first episodes in their 40s and had more atypical symptoms (Table 1). Differences in electrode targeting and placement and stimulation parameters may have also contributed to the observed response variance. The relative contribution of these various factors will require testing of additional subjects. In the future, the possible interactions between DBS and antidepressant medications need to be examined.

In conclusion, Cg25WM DBS appears to be efficacious for TRD. The treatment is titratable; there are objective imaging correlates of response effects; and the procedure is well tolerated. This approach may represent an effective, novel intervention for severely disabled patients with treatment-resistant depression.

Experimental Procedures

Patients

This pilot study included six patients with treatment-resistant major depression, referred by mood disorder specialists (Table 1). The clinical diagnosis of major depressive disorder, major depressive episode (MDD-MDE) was independently confirmed by two psychiatrists and a research coordinator using the Structured Clinical Interview for DSM-IV (First et al., 2001). Patients were selected for surgery because they were resistant to all available therapeutic options. All had failed to respond to a minimum of four different classes of antidepressant medications, prescribed at maximal tolerable doses. Failed treatments included SSRI, venlafaxine, bupropion, monoamine oxidase inhibitor, and tricyclic antidepressants, as well as augmentation strategies using lithium, atypical antipsychotics, and anticonvulsants. Five of the six patients had received electroconvulsive therapy, and all had attempted cognitive behavioral therapy without clinical improvement. Patients with cerebrovascular risk factors or a previous stroke; documented head trauma or neurodegenerative disorders; other Axis I psychiatric diagnoses including schizophrenia, bipolar disorder, panic disorder, obsessive compulsive disorder, or evidence of global cognitive impairment were excluded. Patients with psychotic symptoms, current history of substance abuse, daily use of alcohol in the previous 3 months, or active suicidal ideations were also excluded. Other exclusion criteria included age over 60, pregnancy (risk of radiation exposure from the PET scans), general contraindications for DBS surgery (cardiac pacemaker/defibrillator or other implanted devices), and inability or unwillingness to comply with long-term follow-up. Final selection was made by consensus of the investigator team. Additional subjects were screened but either did

not meet inclusion/exclusion criteria or were accepted but declined.

Informed Consent Process

The study protocol was reviewed and approved by three separate ethics committees at the University of Toronto: Toronto Western Hospital, Centre for Addiction and Mental Health, and Baycrest Centre for Geriatric Care. All potential subjects were referred by a psychiatrist that was not involved in the research protocol. They were then seen independently by two psychiatrists (V.V. and S.K.) for diagnostic assessment and if potentially eligible, introductory discussions took place. In all cases, the referring psychiatrist was involved in discussions of the potential benefits and the potential risks associated with DBS. During subsequent meetings with one of the principal investigators (H.S.M.), a family member was invited to attend and did so in all cases. Only after these discussions, were interested candidates referred to the neurosurgical principle investigator (A.L.), who explained the surgical procedure. Interested candidates were offered informed consent forms to read and further discuss as needed. The average time from initial assessment to signing consent was 6–8 weeks.

Surgery

The general surgical procedure for the implantation of DBS electrodes has been previously described (Abosch and Lozano, 2003). A stereotactic frame (Leksell G; Elekta, Inc., Atlanta, GA) was affixed to the patient's head on the morning of surgery, and preoperative MR images were obtained (Signa, 1.5 tesla; General Electric, Milwaukee, WI). The x, y, and z coordinates of the anterior (AC) and posterior commissures (PC) were determined using axial 3D T1 MR images. To target the subgenual cingulate white matter target, a midline T2 sagittal image was chosen, and the cingulate gyrus below the genu of the corpus callosum was identified (Figure 1, row 1) (Schaltenbrand and Wahren, 1977). A line was traced from the most anterior aspect (genu) of the corpus callosum to the anterior commissure and the midpoint was selected (Figure 1, row 2, left). The T2 coronal section correspondent to the plane of this midpoint was identified, and the coordinates of the transition between the gray and white matters of area 25 were calculated (Figure 1, row 2, right).

In the operating room under local anesthesia, a burr hole was drilled 2 cm from the midline in front of the coronal suture. The underlying dura mater was opened, and the exposed pial surface coagulated. Tisseal (Immuno, Vienna, Austria) was used to prevent cerebrospinal fluid egress and minimize brain shift. The Leksell arc was attached to the head frame and set to the target coordinates. Microrecordings were started 10 mm above the target using electrodes made from parylene-C-insulated tungsten wires and plated with gold and platinum. Tip lengths ranged from 15 to 40 μm and impedances ranged from 0.2 to 1.5 MΩ. Cell activity was amplified (DAM 80 WPI Instruments) with a gain of 1000 and initially filtered to 0.1–10 kHz. The signal was displayed on an oscilloscope and directed to a window discriminator (Winston Electronics) and an audio monitor (Grass AM 8, with noise clipping circuit). In the present study, microelectrode mapping was mainly used to confirm the anatomic location of the gray and white matters of area 25, characterized respectively by the recording of neuronal activity and cell sparse areas. The transition between these two regions was chosen as the final target for the implantation of the electrodes. Final electrode location was confirmed by postoperative MRI (example, Figure 1, row 3).

DBS quadripolar electrodes (Medtronic 3387; Medtronic, Inc., Minneapolis, MN) were implanted bilaterally. Each of the four electrode contacts was tested for adverse effects and clinical benefits. These contacts were numbered from 0 to 3 (right hemisphere) and 4 to 7 (left hemisphere), 0 and 4 being the most ventral and 3 and 7 the most dorsal contacts. The electrodes remained externalized for 5–7 days for clinical testing. They were then connected to a pulse generator (Kinetra, Medtronic, Minneapolis, MN) that was implanted in the infraclavicular region under general anesthesia. Prophylactic antibiotics were used for 24 hr after each of the surgical procedures.

Clinical Evaluation and Follow-Up

Clinical efficacy was evaluated using standardized ratings by the study psychiatrist blinded to the current stimulus parameters and/or changes. Standardized ratings included the Hamilton Depression Rating Scale (HDRS-17 and 24 item versions) (Frank, et al., 1991), the Montgomery Asberg Depression Scale (MADRS) (Montgomery and Asberg, 1979), the Clinical Global Impressions Scale (CGI) (National Institute of Mental Health, 1970), and the Positive and Negative Affective Scale (PANAS) (Watson and Clark 1988) (Table 3). Ratings were performed weekly for the first 3 months and biweekly until the study endpoint at 6 months, following baseline assessments at enrollment and 1 week prior to surgery. Medications were unchanged throughout the 6 month follow-up period.

PET Scanning Acquisition and Data Analysis

Regional cerebral blood flow PET scans (rCBF) were acquired preoperatively and after 3 and 6 months of chronic DBS (Fox et al., 1984). Five CBF scans were acquired in each subject at each time point. A comparative scan-set (one time point only) was also acquired under identical scanning conditions in a group of five age- and sex-matched healthy volunteers. All scans were acquired with subjects resting, with eyes closed and no explicit cognitive or motor instructions. Scans were acquired on a GEMS/Scanditronix 2048b camera (15 parallel slices; 6.5 mm center-to-center interslice distance) using measured attenuation correction (68Ge/68Ga transmission scans). rCBF was measured using the bolus [^{15}O]-water technique (35 mCi ^{15}O-water dose/scan; scan duration 60 s) (Mayberg et al., 1999). Scans were spaced a minimum of 11 min apart to accommodate radioactive decay to background levels. Mood state (sadness and anxiety) was assessed at the end of each scan using a seven-point analog scale and the PANAS to verify behavioral stability over the course of the five scans (Watson and Clark, 1988).

Statistical analyses were performed using SPM99 (Wellcome Department of Cognitive Neurology, London, UK) implemented in Matlab (version 5.3, Mathworks Inc., Sherborn, MA). PET scans were first realigned and then spatially normalized into standard three-dimensional space relative to the anterior commissure using the MNI ICBM 152 stereotactic template within SPM99. The images were then corrected for differences in the whole-brain global mean, and smoothed using a Gaussian kernel to a final in-plane resolution of 10 mm at full-width at half-maximum. Baseline abnormalities (patients versus controls) and changes with chronic DBS (3 months versus baseline, 6 months versus baseline) were assessed using general linear models (peak voxel threshold $p = 0.001$; cluster threshold 50 voxels (voxel = 2 mm^3) (Worsley et al., 1996). Resulting t values were lastly converted to z scores for interpretation. Brain locations are reported as x, y, z coordinates in MNI space with approximate Brodmann areas (BA) identified by mathematical transformation of SPM99 coordinates into Talairach space (http://www.mrc-cbu.cam.ac.uk/Imaging/) (Table 3).

Neuropsychological Testing

A comprehensive battery of neuropsychological tests was administered at three time points to establish baseline intellectual and cognitive abilities prior to surgery/stimulation and to monitor for changes over time (3 months, 6 months). Tests were chosen to tap general cognitive and intellectual function, as well as four domains of frontal function (Bechara et al. 1994; Freedman et al., 1998; Lang et al., 1999; Spreen and Strauss, 1998). Parallel versions were used where possible to minimize effects of repetition, and scores are corrected for effects of age, gender, and education, where appropriate. The following tests were administered: Wechsler Adult Intelligence Scale-III; North American Adult Reading Test; Trail Making Tests A and B; Boston Naming Test; Benton Judgment of Line Orientation Test; Hopkins Verbal Learning Test; Brief Visual Spatial Memory Test, Revised; Finger Tapping Test; Grooved Pegboard Test; Controlled Oral Word Association Test; Wisconsin Cart Sorting Test; Stroop Color Word Test; Emotional Stroop Task; Object Alternation Test; Iowa Gambling Task; and the International Affective Picture System Ratings. A subset of tests is presented. Paired t tests were used to compare differences between the baseline and 6 months data to determine the probability that the actual mean

difference is consistent with zero. This comparison is aided by the reduction in variance achieved by taking the differences, and thus is a good choice for use with a small sample. A more detailed discussion of neuropsychological results will be published separately.

Supplemental Data

The authors' conflict of interest statement can be found online at http://www.neuron.org/cgi/content/full/45/5/651/DC1/.

Acknowledgments

This study was supported by a distinguished Investigator Award to H.S.M. from the National Alliance for Research in Schizophrenia and Depression (NARSAD). We thank Kari Fulton for patient screening and coordination; Doug Hussey and Alvina Ng for acquisition of the PET studies; Jonathan Dostrovsky and William Hutchison for intraoperative electrophysiological studies; Jean Saint-Cyr for assistance with MR imaging; and Stanley Mayberg and Paul Holzheimer for critical review of the manuscript.

THE SIXTH THOMAS JAMES OKEY MEMORIAL LECTURE

Vietnam veterans' rapid recovery from heroin addiction: a fluke or normal expectation?

LEE N. ROBINS

Department of Psychiatry, Washington University School of Medicine, St Louis, Missouri, USA

Abstract

Between 1972 and 1974, the outcomes of army enlisted men who had served in Vietnam during 1970–71 were evaluated and compared with that of a matched group. This paper reports the major findings of that study with respect to frequency of narcotic addiction in and after Vietnam, and the major risk factors for Vietnam addiction and later relapse. Extraordinary access to records facilitated drawing the sample, locating it, and verifying interview responses. The surprisingly low levels of readdiction and the rarity of addiction to narcotics alone as compared with poly-substance dependence are findings still not entirely incorporated into public and scientific views of heroin addiction. Some defenses against that incorporation are examined.

Introduction

When planning this paper, I was asked to look back at my study of Vietnam veterans (Robins, 1973, 1974b) to answer whether at the time I had thought it would be important, and to say how the results have fared over the last 20 years. I am grateful for the opportunity to indulge in this exercise of nostalgia.

The paper will begin by saying something about how the study happened to be done. Then it will summarize how the study turned out both technically and substantively. It will end by saying whether the findings seem to have been correct and generalizable, and if so, whether they have been integrated into the expert or public view of heroin addiction.

Why the Vietnam study was done

Vietnam was linked to the general concern in the United States about drug use from the time soldiers were sent there as 'advisers' in the early 1960s. First the concern was about marijuana. It was not until 1969 that heroin appeared in Vietnam. Rumors of its use by servicemen were confirmed dramatically in 1971 when two congressmen who travelled to Vietnam announced that many servicemen were addicted. Nixon then declared heroin addiction to be the nation's "No. 1 Public Health problem". He created the Special Action Office on Drug Abuse Prevention (SAODAP) in the White House, and tapped Dr Jerome Jaffe to head it. President Nixon persuaded Dr Jaffe to give up his academic life by arguing that wars had stimulated scientific discoveries in the past. Dr Jaffe accepted the argument, and agreed to take up the challenge of controlling heroin use in Vietnam, because if he failed, at least his efforts would yield a good scientific study. In June 1971, he went to Vietnam and established a urine screening program, which required that any man due to leave Vietnam be tested and have a 'clean' urine before

boarding the airplane. Urine initially positive by the FRAT test was to be re-tested with gas chromatography. If the test was again positive, the man was to be sent to detoxification for about a week, and his urine re-tested before he was allowed to leave the country. As soon as Dr Jaffe returned from Vietnam, he invited me to design a study to estimate the size of the problem both in Vietnam and after return.

My selection for the job was based on our having served together as members of the Narcotic Addiction and Drug Abuse Grant Review Committee of NIMH. I had been appointed to this committee based on a single published paper. My first major research effort was a follow-up of a child guidance clinic population and a matched normal control group (Robins, 1966). That study showed an impressive continuity between childhood antisocial behavior and adult outcomes, but I worried about the study's generalizability, because the subjects were patients, all white, and all born between 1907 and 1919. I decided to replicate it in a non-patient, later-born, non-white sample. In 1965–66, I interviewed 235 St Louis-born black men in their early thirties, selected from records of the St Louis elementary schools, which had been racially segregated in their childhoods. In both studies I looked at drug use and abuse as one outcome. While drug use was rare in the first study, the black schoolboys reached adolescence just after World War II, when drugs had entered the black ghettos but had not yet reached middle-class white America. By the time I followed them, illicit drug use had reached the white middle class and was a raging concern throughout the country. Half my sample said that they had used an illicit drug, and 10% said they had been addicted to narcotics. Although that was only 22 narcotics addicts, this was the first study of heroin addiction in a 'non-captive' adult population, i.e. neither in college nor in treatment. The paper reporting on their drug experience (Robins & Murphy, 1967) led to an invitation to serve on the Narcotic Addiction and Drug Abuse Grant Review Committee.

When Dr Jaffe invited me to do the Vietnam study, I was captivated. When I went to discuss it with him at the SAODAP office and found him working all hours, I began to realize the study might be important politically, as well as scientifically.

Why the study was a technical success

The study went well, helped by the government's concern about having exposed so many young men to what was viewed as a scourge.

It was possible to draw a sample representative of all enlisted Army men who left Vietnam in September 1971, the first month urine screening was in operation throughout the country. We selected two samples, one from a tape of 22 000 men made for us by the Department of Defense (DoD) from the computerized Active Duty Roster of November, 1971. That roster was purged every month of those discharged 4 months before. Thus, the November 1971 tape still contained all men in service in September. Men were selected if they were listed as leaving Vietnam that month. We were able to enrich the number of heroin users in the sample by sampling as well from records of those who tested positive at departure, records held in the Surgeon General's office. The military records of both groups were then checked to verify their departure dates. From Selective Service records, we were able to draw a sample of draft-eligible civilians who did not serve but matched the veterans with respect to age, region lived in, and education at the time the veterans entered service. The high level of cooperation from the subjects made possible a remarkably high interview completion rate, 96% when the veterans had been back 8–12 months, of whom 94% were then re-interviewed 3 years after their departure from Vietnam.

We also had access to all the record information we needed from the military and the Veterans Administration. These records, plus testing the urines we collected at the end of each interview, allowed us to verify what the men told us in interviews. These checks showed remarkable honesty: 97% of those whose military record showed narcotics use told us about their use while in service, and tests of urine samples collected at the end of the interview showed no higher rates positive for current use than did their self-reports given before they knew they would be asked for a urine sample.

We were able to complete the first interviews within a 6-month period, which both enabled us to provide information to the Government promptly, and meant that the men all had had approximately the same length of time at risk of relapse between return and interview. We reinterviewed the veterans and the comparison

sample when veterans had been back 3 years to learn whether the initial results would hold over time.

We began to feel confident about our sampling strategy when the DoD was not upset by our estimate that the number of men who returned in September 1971 was only 13 280, rather than the 22 000 on the tape given us. Our lower estimate was based on finding that many of the men we initially selected from the tape had to be dropped because their military records showed either that they never served in Vietnam or that they had left before September. While we were in the field, the DoD revised their estimate of men who returned in September based on lading documents from the airplanes that brought the men home, and we had hit within 3% of the revised number!

The study's assets

(A) A number of factors led to the high co-operation rate and the accuracy of our estimates. First, Dr Jaffe had involved multiple agencies—the National Institute of Mental Health, the Department of Defense, the Veterans Administration, and the Department of Labor—in its funding. This opened all the files we needed for sampling and follow-up.

(B) Urine testing in Vietnam had begun in July, 1971, 2 months before we designed the sample. This 2-month experience with testing had informed the DoD that the vast majority of heroin users were Army men below the officer level, and they advised us to restrict the study to this group.

(C) Being able to sample from the Surgeon General's list of men who had tested positive allowed us to over-sample heroin users so that we interviewed over 600 men who used narcotics in Vietnam. It also enabled us to estimate the proportion detected as drug-positive by the military at departure. Duplications between those we sampled from the Surgeon General's list and those we sampled from the Active Duty Roster gave us the needed data. Knowing the proportion positive then allowed us to weight the over-sample of positives back to their true representation in the population.

(D) All service records of those discharged happened to be stored in St Louis, making it convenient for us to review the complete military record to check whether the man had actually served in Vietnam and left in September, 1971. This turned out to be very important because the Army was in a 'stand-down' phase, during which manpower in Vietnam was being reduced by shortening the scheduled 1 year tour of duty there. Many of the names on our 'September' departure tape belonged to men who had actually left earlier. The military record also provided name and addresses of the next of kin, which helped us locate the man, as well as information about disciplinary actions and reported drug use, against which we could check honesty of the interview.

(E) Even though the men selected lived all over the US, and a few were stationed overseas, they were not difficult to find. Those who entered via the draft were drafted at 18 for 2 years. They typically arrived in Vietnam at age 19 after almost a year Stateside, served in Vietnam for 1 year, and were discharged soon after return, at 20 or 21. At this age, most could still be reached at their parents' home. The men who enlisted voluntarily had a 3-year obligation, and more of them signed up for another term of service. The military's Worldwide Locator made it possible to locate them at their current station.

(F) We had excellent support from the National Opinion Research Center, the group selected to carry out the interviewing. This was my first experience with employing an interviewing organization; on previous studies, I had hired and supervised interviewers myself. However, this study required rapid completion. An excellent study director and field director were willing to do extraordinary things, such as shipping interviews to Canada to preserve confidentiality through a double-link file, and collecting urines and shipping them to Canada for confidential testing. These extraordinary precautions to preserve confidentiality were vital to the enthusiastic cooperation of the interviewers, who were very concerned about possibly harming the veterans. (The men themselves seemed remarkably unconcerned.)

(G) A delay in funding, that looked ominous initially, turned out to be helpful in the end. Dr Jaffe had originally asked that we interview the men when they had been back 2–3 months. The funding delay meant that they had been back 8 months before we could enter the field. This delay gave them time to be discharged and return home, making them easier to find. It also made the findings more meaningful. If they

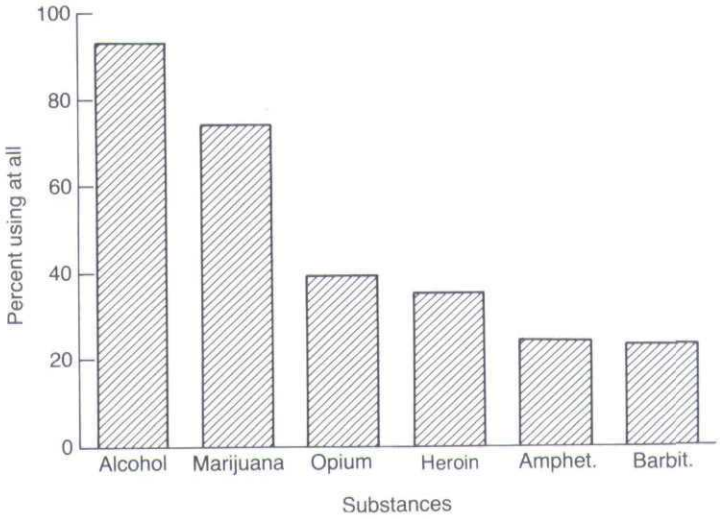

Figure 1. *Substance use in Vietnam.*

wanted to use heroin in the States, they had had ample time to locate a supply and begin to use it.

(H) Before the 3-year follow-up was due, the draft ended and selective service registrations were moved to a few Federal Records Centers. This made the location of civilian control subjects a great deal more efficient than if we had had to approach the Draft Board in each subject's home town to find a civilian who matched him. The DoD even provided us with members of Army Reserve Units, who spent their required yearly 6 weeks of active duty in going to the Federal Records Office to select civilian matches for our second follow-up. This overcame the problem that as civilians we could not legally have access to Selective Service records (although we accompanied the Reservists to be sure they selected cases properly.)

I believe these were the reasons that the study went well, along with the veterans' wish to be heard. But a technically successful study is exciting only if the results are interesting. Let me summarize what I see as the five major findings.

The major findings

(1) First, the DoD had greatly underestimated the size of the narcotics problem in Vietnam. Almost half (45%) of Army enlisted men there in 1970–71 tried narcotics; 34% tried heroin and 38% tried opium. While fewer used heroin or opium than alcohol or marijuana (Fig. 1), narcotics were used at a truly astounding rate. These figures reflect the fact that these drugs were cheap—even an addict need spend only about $6.00 per day—and pure—they need not be injected, a method which repelled many soldiers. Instead heroin could be mixed with tobacco and smoked. That opium was used so widely was a particular surprise; the press had reported only on heroin use.

Addiction was also more common than reported—20% claimed that while in Vietnam they had felt strung out or addicted to narcotics. To see whether that claim really meant physiological addiction, we asked for frequency and length of use and withdrawal symptoms. Those who claimed addiction had almost all used narcotics heavily for a considerable time and suffered the classic symptoms of withdrawal for at least several days. We concluded that their claims of addiction were correct.

Almost 11% of Army enlisted men's urines tested positive at departure. If the urine screen captured only those so addicted they could not stop their use when warned that they would be screened, as Dr Jaffe intended, this would mean that about 1400 recently or still addicted enlisted soldiers were arriving in the US per month (plus a small number of addicted officers and enlisted personnel in other branches of the military).

Serving in Vietnam was associated with greatly increased use of marijuana as well as narcotics; close to 80% of enlisted men used marijuana while in Vietnam. Other drugs were used too, but it was use of marijuana and narcotics that

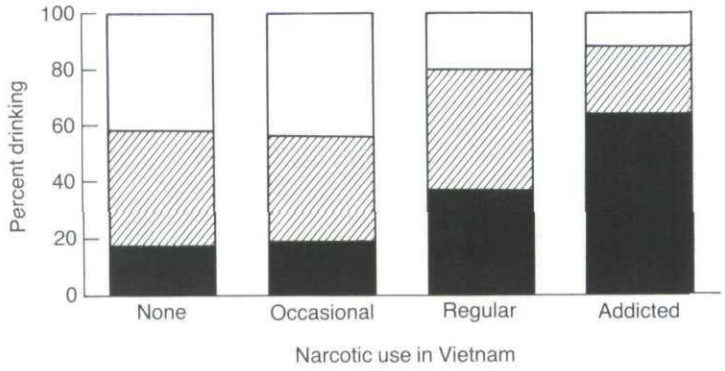

Figure 2. *In Vietnam, narcotic use and drinking were inversely related (Drinking frequency: ■ less than monthly; ▨ less than daily; □ daily).*

was distinctively greater in veterans than in the comparison sample.

(2) A second finding was that the orderly sequence of substance use described as a Guttman scale, in which no one progresses to an illicit drug without having used the legal drugs, alcohol and tobacco, and no one progresses to a 'hard' illicit drug without having used a 'softer' illicit drug (Kandel, 1975), had been turned topsy-turvy in Vietnam. Before and after Vietnam, heavy alcohol use was almost a prerequisite for narcotic use; in Vietnam, they were inversely correlated (Fig. 2). (This may have been explained by military rules against selling alcohol to soldiers under 21; for the average enlisted man, who arrived in Vietnam at 19, heroin was more available than alcohol.) This displacement from the expected sequence also occurred for amphetamines. Before service, amphetamines were often used without narcotics or barbiturates, but narcotic use virtually never occurred without amphetamine use. In Vietnam, amphetamines were essentially used *only* by users of barbiturates and narcotics. These sequence reversals show that a drug's position in the sequence has more to do with its availability than either with its intrinsic 'hardness', by which I think we generally mean its addiction liability, or with popular beliefs about its dangerousness.

(3) In my study of young black men, I had found a history of deviant behavior strongly associated with drug use (Robins & Murphy, 1967). One might have expected the much greater availability of drugs in Vietnam and stresses of serving in a war to break the link with deviance. But they did not. The same relationship between early behavior problems and drug use held in Vietnam. We counted occurrence and severity of five pre-service behaviors: fighting; truanting; drunkenness; arrest; and school expulsion. Each was scored as not present, present mildly, or present at a serious level. Both a larger number and greater seriousness increased the risk of using narcotics in Vietnam (Fig. 3).

(4) In the first year after return, only 5% of those who had been addicted in Vietnam were addicted in the US (Fig. 4; Robins, Davis & Nurco, 1974b). This finding was totally unlike the outcomes of young men treated in Lexington, the Federal Narcotics Hospital at the time. When those young men were followed 6 months later, two-thirds were found to already be re-addicted (Stephens & Cottrell, 1972). Even veterans still on narcotics at departure from Vietnam were doing very well 8–12 months after return. The curve showing the likelihood of any use, heavy use, and addiction for veterans was the mirror image of that for treated civilians. Nor was this good result transient. When we followed veterans at 3 years, only 12% of those addicted in Vietnam had been addicted at any time in the 3 years since return, and for those re-addicted, the addiction had usually been very brief.

It was not treatment that explained this remarkable rate of recovery. Only a third of the men addicted in Vietnam received even simple detoxification while in service, and only a tiny percentage of Vietnam enlisted men went into drug abuse treatment after return—less than 2% of those who used narcotics in Vietnam, 6% of those who were positive at departure, and 14% of those positive at departure who continued to

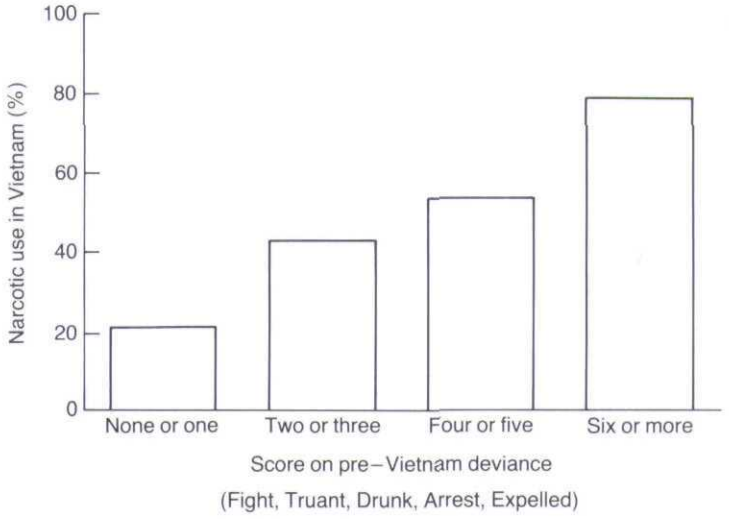

Figure 3. *Behavior before Vietnam and narcotic use in Vietnam.*

use after return (Robins, 1975). Yet, those who *did* enter treatment had relapse rates as high as the young civilian men in Lexington—two-thirds had relapsed by the time we interviewed them. Relapse often occurred the very day they left the hospital (Fig. 5).

Nor did recovery require abstention. Although nearly half the men addicted in Vietnam tried narcotics again after return, only 6% overall got re-addicted (Fig. 6). Some were spared by using only narcotics other than heroin; some by not injecting, some by using only occasionally. But even regular heroin users became re-addicted in only half the cases (Robins *et al.*, 1980).

This surprising rate of recovery even when re-exposed to narcotic drugs ran counter to the conventional wisdom that heroin is a drug which causes addicts to suffer intolerable craving that rapidly leads to re-addiction if re-exposed to the drug.

(5) In the US, many drug programs have been set up especially for heroin addicts, for whom methadone, experimental narcotic antagonists, or group therapy is provided. We found little evidence for a group of veterans whose main problem is heroin addiction (Robins *et al.*, 1978). Those who used heroin after return were also using a great variety of other drugs. More than 80% used amphetamines, more than 70% used barbiturates, and almost all used marijuana. Those addicted to heroin often had multiple dependencies. When heroin addicts were asked what their 'main' drug was, more than half named alcohol or marijuana rather than heroin.

We found little to justify the view of heroin as an especially dangerous drug. Heroin *was* associated with more adverse outcomes (crime, unemployment, illegal employment, divorce or separation, violence, transiency, credit problems, alcohol abuse, drug problems) than barbiturates and amphetamines, but *not if pre-service behavior problems and the number of other types of drugs used was held constant.* When they were, barbiturates and amphetamines were associated with as many problems. Indeed, the *variety* of drugs used was a better predictor of adverse consequences than *which* drugs were used.

These then were the major conclusions: narcotic use and narcotic addiction were extremely common in Vietnam (although not as common as use of alcohol and marijuana); availability was the main explanation; those with a history of deviant behaviour *before* Vietnam were particularly at risk; addiction was rare and brief after return, even when men continued to use narcotics; veterans re-addicted *and entering treatment* had as high a relapse rate as civilians; and heroin's adverse effects were no greater than those of amphetamines or barbiturates when juvenile behavior and concomitant use of other drugs was taken into account.

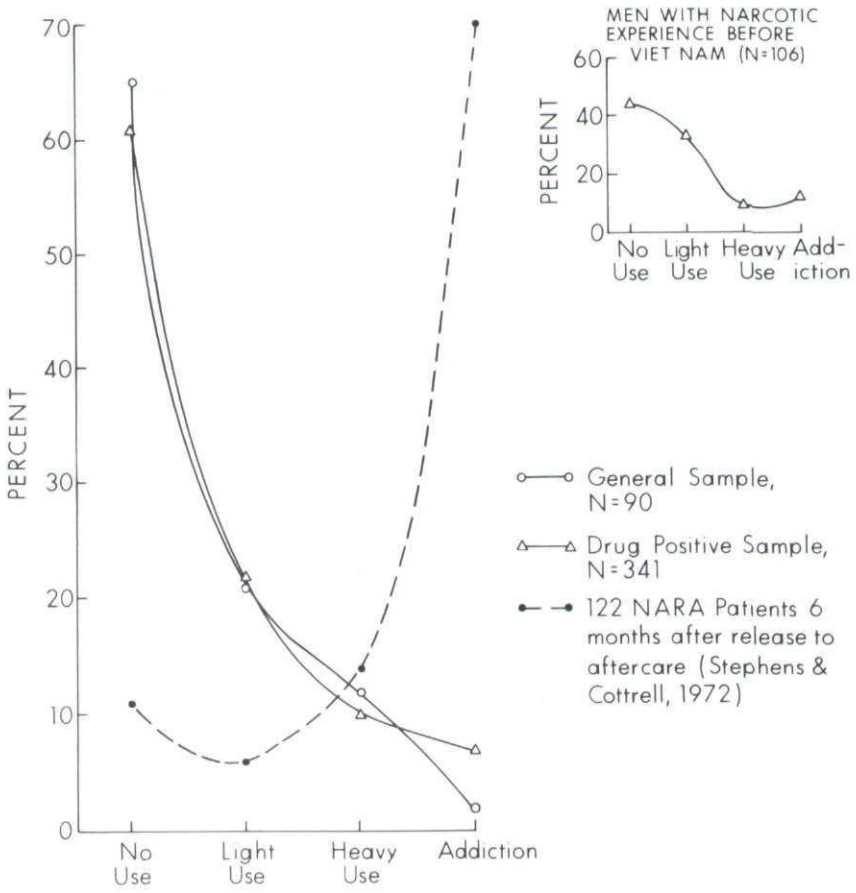

Figure 4. *Narcotic use in the 8–10 months post Vietnam by men first addicted in Vietnam.*

The response to the study by the DoD, the press, and the research community

Even though our study showed that the amount of heroin use in Vietnam had been underestimated, the DoD was pleased with the findings, because they showed that Vietnam veterans had not been consigned to a life of unrelenting dependence on drugs. (Our only problem was with one general who wanted to take credit for having cured the addicts with a little Valium during detoxification, and claimed that our study proved that methadone maintenance was unnecessary.)

The press and the research community were more skeptical. They resisted giving up the beliefs that heroin was a uniquely dangerous drug, to which a user became addicted very quickly, and addiction to which was virtually incurable. They maintained these beliefs by offering three interpretations of our findings:

(1) The results could be wrong. Perhaps the findings were tailored to exonerate the DoD; the men might have been addicted after return more often than we reported. (The suspicion that the results were politically manipulated may have been encouraged by the DoD's insistence on sponsoring the press conference which announced initial results.)

(2) Addiction in Vietnam was explained by the extraordinary setting—the misery of war that made addiction a 'normal' reaction; so the relatively benign outcome of addiction in Vietnam was irrelevant to addiction in the US.

(3) The drop in addiction on return was

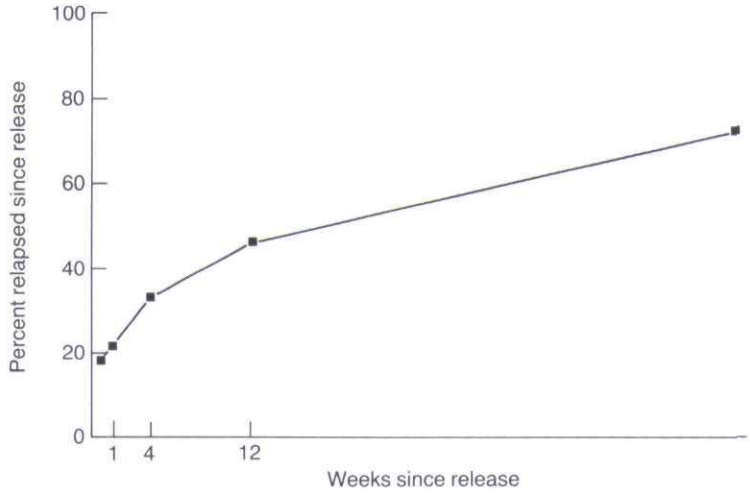

Figure 5. *Relapse to drug use following VA in-patient treatment.*

caused by a change in setting. In the US these men would not know where to get heroin, and the settings in which they lived and worked would not be associated in their minds with use or withdrawal symptoms, and therefore would not serve as stimuli to relapse. Thus again, the study findings would be irrelevant to addiction beginning in the US.

I will argue that each of these views fails to fit the facts.

(1) The idea of a whitewash by the DoD was extensively investigated by a New York Times (NYT) reporter who had recently returned from the newspaper's Saigon office. He was following up on a NYT news story in which a number of scientists had commented on the study, some with doubts about the results. During the 2 months' preparation of his article, he went over the study in great detail, often calling me to challenge what he took to be discrepancies between statements in my report. I spent a lot of time explaining how the results had been reached, and that percents *should* differ when the group being described shifts from the whole population of enlisted men to sub-populations, such as men who had already used drugs before arriving in Vietnam. When the article finally appeared, the Vietnam study was barely mentioned in it. To get only one line in the two-page story that had been intended as an exposé showed that he could not support suspicions of a DoD whitewash.

Of course, the idea that there was a high rate of addiction after return was even more definitively disproved by the failure of veterans to apply for treatment. One of the original motivations for the study was the VA's concern that returning addicts would overtax their services; but the anticipated large demand never occurred. A small increase in cases occurred only because of a change in DoD regulations a few months after the men's return, allowing the Army to delay discharge by 30 days, which drug-positive soldiers would spend at a VA drug treatment program. The DoD wanted men to become familiar with the VA system so that they would return to it if they relapsed. However, they arrived at the hospital already detoxified, and in no obvious need of treatment. The VA generally transferred them to the hospital nearest their homes and allowed them to go home on leave, while remaining on the hospital books as patients, as required by the regulation.

(2) The argument that addiction in Vietnam was a response to war stress, and therefore remitted on exit from the Vietnam war theatre, is still frequently cited as though it were self-evident, because it sounds so plausible. Yet accepting this argument is difficult in the face of the facts: Heroin was so readily available in Vietnam that more than 80% were offered it, and usually within the week following arrival. Those who became addicted had typically begun use early in

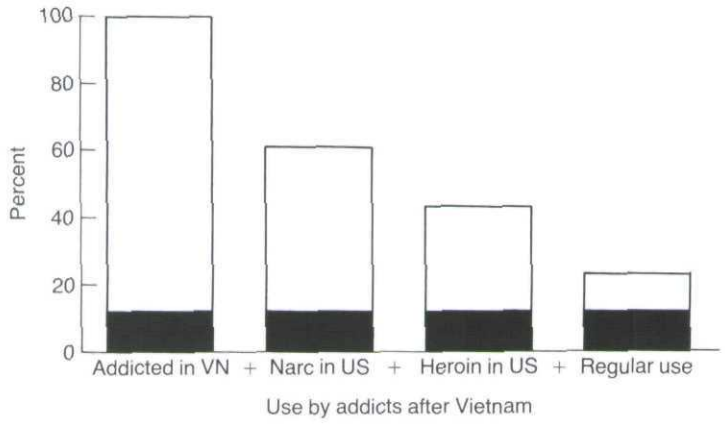

Figure 6. *Risk of re-addiction depending on degree of exposure (■ re-addicted; □ not re-addicted).*

their Vietnam tour, before they were exposed to combat. Further, the dose-response curve that is such a powerful causal argument did not apply: those who saw more active combat were not more likely to use than veterans who saw less, once one took into account their pre-service histories. (Those with pre-service antisocial behavior both used more drugs and saw more combat. Their greater exposure to combat was presumably because they had none of the skills that kept cooks, typists, and construction workers behind the lines.)

While combat had little effect, deviant behavior before service was a powerful predictor, as we have seen. So was pre-service drug experience (Fig. 7); the greater the variety of drugs used before entering service, the greater the likelihood that narcotics would be used in Vietnam. Like the St Louis-born young black men we studied earlier, the best predictors for use of narcotics in Vietnam were earlier antisocial behavior and experience with precursor drugs.

Finally, when we asked men why they used heroin, they did not tell us that they were overcome by fear or stress. Rather, they said it was enjoyable and made life in service bearable (Table 1).

(3) The argument that men addicted in Vietnam would not relapse because they would not be re-exposed in the US to stimuli associated with their drug use and withdrawal symptoms experienced abroad is based on Abraham Wikler's conditioned response theory of relapse (Wikler, 1973). This theory has been the basis for successful treatment programs, which gives it empirical support. However, it fails to account for the fact that among the one-half of the Vietnam addicts who *did* use heroin after their return, most did not become re-addicted, and those who did become addicted were addicted only briefly. Only one-fourth of those re-addicted by the time of their first interview at 8–10 months after return were addicted at any time in the next 2 years, even though, having been addicted in the US, they presumably had the opportunity to develop conditioned responses to the US stimuli associated with addiction and withdrawal (Fig. 8). Their claim not to be still addicted was validated by finding few of them to have positive urines at either the first or the second follow-up interview.

Where to the Vietnam study's findings stand now?

What then are my views of heroin addiction twenty years after the Vietnam study? I have still not found a serious flaw in the study, and I think the findings are consistent with those of other studies. For example,

(1) Charles Winick (1962), using the Federal Bureau of Narcotics records and the New York Narcotics Register, found that names tended to drop off at ages 35–40, or after 5 years. Because he carried out no personal interviews, he could not prove that his critics were wrong when they argued that the addicts had left town or died or somehow managed not to get caught again. However, he believed that they had 'matured out'—i.e. recovered spontaneously.

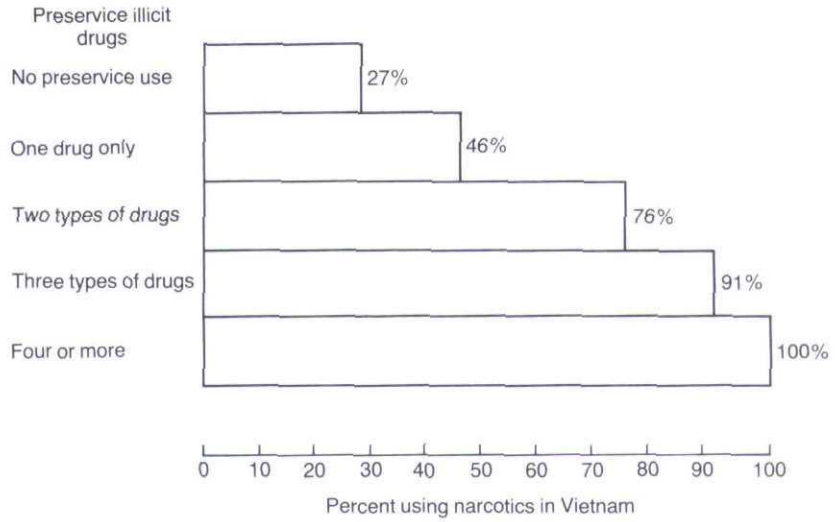

Figure 7. *Preservice drug experience and use of narcotics in Vietnam.*

(2) Waldorf & Biernacki (1979) did an ethnographic study of 50 untreated heroin addicts who had been free of addiction for at least 2 years, and reported that the median duration of their addiction had been only 5.7 years.

(3) Our own small study of young black men (Robins & Murphy, 1967) included 22 who reported having been addicted to heroin. Only four of these addicts had used any heroin at all in the year prior to interview at age 31–35. And only four had had any treatment. Heroin addiction for them, as for Vietnam veterans, was associated with use of a large number of other drugs. Like the Vietnam veterans, they experienced an accretion of drug types, not a 'stepping stone' pattern of moving from milder to stronger drugs. Indeed, heroin use preserved, rather than replacing, the use of other drugs.

(4) A study of young men 18–28 registered with Selective Service (O'Donnell *et al.*, 1976), conducted at the same time as our 3-year follow-up of veterans, showed that only 13% of those reporting heroin use had had any treatment, and only 27% of the untreated had used heroin within the last year, while 65% of the treated had. This suggested that treated cases are those who cannot stop on their own—and often do not stop when treated.

Table 1. *Why men used narcotics in Vietnam*

Reason volunteered	%
To feel high	40
Tolerate Army regulations	13
Relieve boredom	9
Relieve depression	9
Relieve fear	8
Pass time	5
Be one of the group	3

(5) A follow-up of Harlem youth (Brunswick, 1979) showed that only 25% of young people 18–23 who had used heroin twice or more had used any in the current year; the rate of recent use was particularly low among the untreated—16%.

(6) Norman Zinberg identified a group of 'chippers'—recreational users of heroin who never became addicted (Zinberg & Jacobson, 1976).

(7) The Epidemiologic Catchment Area study of all major psychiatric disorders in random samples of US adults in five geographic areas asked all affected the age of first symptom and the age of most recent symptom, and whether they had ever discussed their illness with a physician (Robins, Locke & Regier, 1991). Subtracting age of first problem from age at the last problem gives an estimate of duration. Substance abuse had the shortest mean duration of any of the psychiatric disorders—only 2.7 years. And only one in five of those dependent on or abusing an illicit drug had had any treatment. Most of these cases were not heroin addicts; marijuana was the most common drug of abuse. Still, this study

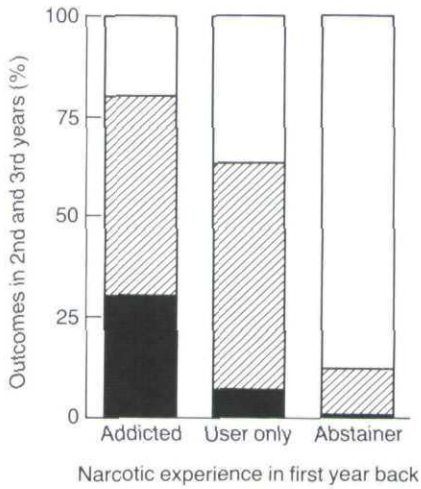

Figure 8. *Fate of year 1 addicts, users, and abstainers in the next 2 years (■ addicted year 2–3; ▨ user, non-addict; □ abstainer, year 2 and 3).*

shows that drug addiction tends to remit quickly, even in the absence of treatment.

So, I am unrepentant. I think the results were both correct and not unique. This is not to deny that the Vietnam situation was one quite unknown previously. Surely there has never been a time when so many young men were addicted to opiates in the absence of typical risk factors. Few of the Vietnam addicts would have become addicted if they had remained in the US. However, their history of brief addiction followed by spontaneous recovery, both in Vietnam and afterwards, was not out of line with the American experience; only with American beliefs. Nor was their ability to reuse without becoming re-addicted very unusual.

I think there are three important implications for policy in this study, which still have not been fully incorporated into our understanding of heroin addiction. First, addiction looks very different if you study it in a general population than if you study it in treated cases. The small number of Vietnam addicts who came to treatment relapsed as rapidly as do other young men in treatment. Their having become originally addicted as a response to stress or in an exotic situation was of no help to them. Those who did not come to treatment were able to get themselves off heroin without help. The implications are first, that heroin addicts are not doomed for life, and should be helped to remain in or re-enter conventional society, and second, that drug users who appear for treatment have special problems that will *not* be solved just by getting them off drugs.

Second, I think the evidence that heroin is not an exceptional drug has stood the test of time. Its association with long-term addiction and crime appears to be as much a function of its bad reputation, that relegates its use chiefly to people with little regard for social proprieties, as to its intrinsic effects on brain and behavior.

Third, at least in the US, the 'heroin addict' for whom current treatment programs are designed is a mythological creature. Most users of heroin use many substances, and may be as or more dependent on one of these other drugs as on heroin. They are almost all (in the US) also dependent on alcohol and tobacco. Yet treatment slots are still mainly available for heroin use and heroin users. In the Epidemiologic Catchment Area study conducted in the early 1980s, we found that persons with heroin problems in the last year had a reasonable chance (35%) of being seen in a drug treatment facility. Those with problems with other drugs only were very unlikely to receive treatment in a drug program (less than 2% did). Yet they were only a little less likely than those with heroin problems to receive some kind of psychiatric care (Fig. 9). The segregation of treatment by drug type seems misguided to me. It is no wonder that drug

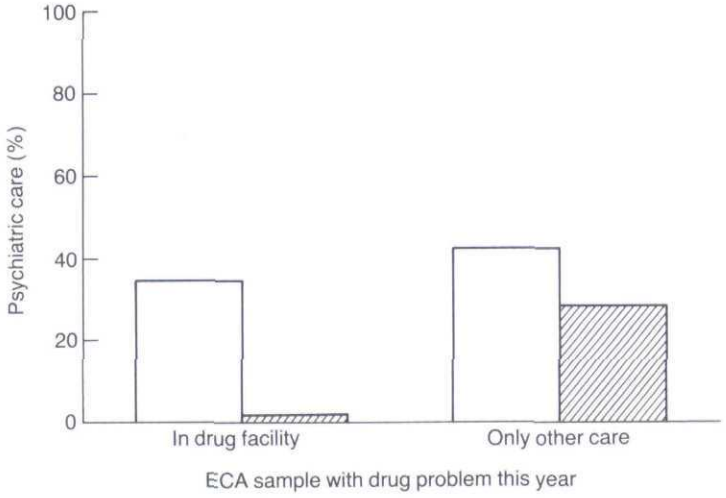

Figure 9. *Treatment this year; heroin (□) vs. other illicit drugs only (▨).*

treatment is not more successful when only a small part of the total problem is being addressed.

As I look back at the Vietnam heroin experience, I conclude that soldiers had no special readiness to use narcotics or to recover from addiction to them. Their remarkable rate of use was a response to market conditions—both the high availability of opiates and the lack of alternative recreational substances, to the absence of disapproving friends and relatives, and to the fact that serving in Vietnam was not seen as part of their real-life career. Their readiness to recover from addiction did not differ from that of other users. The reason that the press and scientists alike were surprised was because studies of the general population's drug dependence were and continue to be so rare. Their expectations were based on the rates of relapse found in patient populations, made up of addicts who tried but failed to get themselves off drugs.

It is not likely that the lack of general population studies will be remedied. Even large studies of general populations, such as the National Institute of Drug Abusers regular National Household Survey of Drug Use and yearly Monitoring the Future, which follows high school seniors into adulthood, do not study addiction because there are too few cases. The Epidemiologic Catchment Area study, committed to the study of disorder, not just use, reported on drug abuse and dependence as a whole because only 0.7% of the population met criteria for opiate abuse or dependence.

Beliefs about heroin based entirely on results in treated populations have created a self-fulfilling prophecy. Heroin is or was (perhaps now surpassed by 'crack') thought of, by law enforcement personnel and users alike, as the 'worst' drug, virtually instantly and permanently addictive and creating craving so extreme that it overcomes all normal ability to resist temptations to theft and robbery to acquire it. Users who share that view show by their use that they are ready to commit themselves to their concept of an addictive life style. The public's ranking of drugs with respect to 'hardness' probably has more to do with the drug's legal status, the government's commitment to discouraging its use, and its price than with any intrinsic addictive liability. This is best demonstrated by tobacco, a highly addictive drug ranked as 'soft'.

The fact that heroin addiction is not always interminable is still being 'discovered', even by scientists. Just last year the Neuroscience Institute at Harvard University published an article entitled "Addiction: What Science Knows" (Hyman, 1992). It reassured readers that *craving* does not condemn the user to indefinite use: "In the past, it was thought that physical withdrawal symptoms appearing with drug cessation were the key indicators of drug addiction . . . (Now, i)ndeed, despite the 'common wisdom', avoidance of physical withdrawal appears to be a

Table 2. *Variables that failed to predict re-addiction among veteran addicts who returned to narcotics*

Combat
Military discipline problems
Demographic characteristics

relatively minor factor in maintaining addiction even for . . . opiates . . ." But the article still supported the view that addiction is largely irreversible. Accepting *this* 'common wisdom' triggered straining after some biological basis for an irreversibility that may well not exist: "What causes the compulsive use? . . . (O)piates tap into (a) critical circuit in the ventral tegmental area . . . that interacts with the nucleus accumbens and . . . the cerebral cortex . . ., the 'brain reward pathway' . . . With repetitive drug use the brain reward system . . . undergo(es) adaptive changes involving . . . dopamine . . . When the drug is taken away, these neurons now function abnormally, producing dysphoria and intense drug craving . . . for many years." The author is too sophisticated to think that dopamine is the *whole* story: "Factors relevant to individual vulnerability include . . . heredity, . . . unknown developmental factors, . . . other psychiatric disorders, . . . pain, . . . stress. Sociocultural factors also . . . modify the risk of addiction, includ(ing) drug availability, and pressures for or against drug use in one's family, subculture or peer group."

Such a complicated explanation for a belief that addiction liability is relatively permanent is very difficult to test, particularly when the facts indicate that such permanence is rare rather than universal. The solution to achieving some simplification may lie in shifting our focus from addiction as a unitary phenomenon to the transitions between use, addiction, and recovery. In the Vietnam study, the social and behavioral variables that had been so useful in explaining who would *use* narcotics enough to become addicted to them in Vietnam and which ex-addicts would use them again after they returned to the US were of no use at all in explaining which relapsers would become re-addicted (Table 2). Vulnerability to re-addiction *if re-exposed* may indeed be biological. We don't know whether that biological vulnerability is present from birth or created by action of the addictive substance on the brain, as the Newsletter article suggested. What we *do* know is that *different* factors operate at each of the critical transitions: from the drug naive state to use; from use to addiction; from addiction to remission; from remission to relapse.

Abstract

The mechanism of memory remains one of the great unsolved problems of biology. Grappling with the question more than a hundred years ago, the German zoologist Richard Semon formulated the concept of the engram, lasting connections in the brain that result from simultaneous "excitations", whose precise physical nature and consequences were out of reach of the biology of his day. Neuroscientists now have the knowledge and tools to tackle this question, however, and this Forum brings together leading contemporary views on the mechanisms of memory and what the engram means today.

The cellular basis of memory

Mu-ming Poo

Neurobiological studies of memory over the past century have progressed along two relatively independent lines of inquiry: the top-down approach examines the animal's behaviors associated with memory acquisition, consolidation, and retrieval, as well as the brain regions underlying these processes, whereas the bottom-up approach explores the cellular and circuit mechanisms of memory encoding and storage by examining the patterns of neuronal firing and the efficacy of synaptic transmission. In his monumental treatise [1] *The Organization of Behavior* (1949), Donald Hebb made a bold attempt to link these two lines of inquiry by postulating that perceptual memory resides in specific "cell assemblies" formed by the strengthening of interneuronal connections due to correlated activities during memory acquisition. The discovery of activity-induced long-term potentiation (LTP) and long-term depression (LTD) of central synapses in the 1970s and 80s further sparked the interest of a whole generation of neurobiologists in studying synaptic plasticity and its relationship to memory. There is now general consensus that persistent modification of the synaptic strength via LTP and LTD of pre-existing connections represents a primary mechanism for the formation of memory engrams. In addition, LTP and LTD could also lead to the formation of new and elimination of old synapses and thus changes in structural connectivity in the brain. Indeed, early development of neural circuits, whereby neural activity sculpts synaptic connectivity [2], depends on processes similar to that associated with LTP and LTD in the adult brain and could be considered as the imprinting of memory engrams generated by early experience.

In this Forum, a group of experts on the cellular mechanisms of memory were invited to present their views on "what is memory", including where and how memory engrams are stored, consolidated, and retrieved. Drawing on an elegant set of studies, Michele Pignatelli, Tomás Ryan, and Susumu Tonegawa illustrate how recently developed techniques to tag and manipulate neurons have begun to establish a causal link between neuronal activity, persistent synaptic changes, and an animal's memory-associated behaviors. The theme of persistent synaptic changes and their causal role in memory is taken up by Tobias Bonhoeffer, who summarizes the evidence that dendritic spines, where excitatory synapses are located, represent the basic cellular unit for memory; long-term memory is stored in a set of spines that are formed or modified during learning and these changes may persist throughout the animal's life.

Based on the findings of activity-induced transcriptional activation and synapse-specific local translation of proteins, Kelsey Martin expands on the idea that the basic building block of memory is the synapse, where

both pre- and postsynaptic elements together with associated glial processes form an integral unit with an individual identity and distinct "neighborhood". Andrii Rudenko and Li-Huei Tsai redirect attention to the nuclei of engram cells, discussing the evidence that epigenetic alterations of the neurons activated during memory acquisition may be involved in the long-term retention of memory. They propose that such epigenetic modification represents a priming event during the initial phase of memory formation; memory retrieval would then trigger the expression of the primed genes, leading to protein synthesis and synaptic modification at individual synaptic units.

Depending on the availability of cellular resources, immediate modifications (LTP and LTD) and long-term turnover (formation and elimination) of individual synaptic units are bound to influence other units on the same postsynaptic cell. Richard Tsien, Gord Fishell, and Caitlin Mullins focus on the important issue of lateral synaptic interaction and redistribution of synaptic strength associated with LTP and LTD, from the point of view of cellular homeostasis as well as the normalization and signal-to-noise ratio of neuronal activities, and propose a conceptual scheme to address the underlying mechanisms.

The hippocampus is unique in being a key brain region for memory formation and a region in which adult neurogenesis occurs. Associated with hippocampus-dependent spatial memory, Tiago Gonçalves, Matthew Shtrahman, Stephen Johnston, and Fred Gage discuss an intriguing new dimension in the cellular mechanisms of memory formation, whereby continuous addition of newborn dentate gyrus neurons in the adult hippocampus, with their enhanced synaptic plasticity, may contribute significantly to establishing the engram for spatial memory.

As proposed by David Marr in his model of hippocampus-dependent memory [3] and supported by many experimental and clinical studies, episodic memories are transferred after acquisition from the hippocampus to the neocortex for long-term storage. The mechanisms underlying the transfer and consolidation of spatial memory are discussed by John Long and György Buzsaki in the context of hippocampal and entorhinal sharp wave-ripples. These activity patterns occur during sleep or non-attentive brain states and are replays of neuronal firing sequences triggered by recent experience, for example they can be temporally compressed replayed versions of the sequential neuronal firing seen as the animal traverses through a particular environment. As discussed by myself and Yang Dan, although spike timing-dependent plasticity could offer a synaptic mechanism for storing sequence information with intervals up to a few hundreds of milliseconds, it remains largely unknown how neural circuits store and recall the temporal sequence of information up to seconds and longer, periods often associated with episodic memory. A compression of the temporal sequence of events such as occurs during sharp wave-ripples in the hippocampus and neocortex offers a potential solution.

The contributing articles of this Forum reflect the tremendous progress made in our understanding of the cellular building blocks of memory. There is a clear consensus on where the memory engram is stored—specific assemblies of synapses activated or formed during memory acquisition—and a substantial body of knowledge on how the engram is generated and maintained in the brain. However, knowing the building blocks and their properties is far from understanding the architecture of the "memory palace". As Charles Stevens indicates in his epilogue, and the readers will soon discover, many new territories are now open for exploration.

Engram cell connectivity as a substrate for memory storage

Michele Pignatelli, Tomás J. Ryan, and Susumu Tonegawa

The storage of information refers to the systematic process of collecting and cataloging data so that they can be retrieved on request.

One of the most enlightening conceptualizations of the neural representation of stored memory information was developed by Richard Semon, who conceived the Engram Theory, a theory of memory traces [4]. According to this theory, as fortified by contemporary knowledge, learning activates a small ensemble of brain cells, inducing in these cells persistent physical/chemical changes. In addition, reactivation of these cells by relevant recall cues results in retrieval of the specific memory. The theory poses an important question: what is the nature of the persistent changes?

In his seminal book published in 1949, Donald Hebb proposed a mechanism based on synaptic plasticity as a substrate of memory [1]. With an example of two cells connected by an excitatory synapse, if the activation of one cell leads to the activation of the second one, the connection between the two cells is reinforced, a postulate that has been confirmed experimentally [5–8]. The increase in connectivity strength within a diffuse group of cells in a more complex feedforward circuit results in the emergence of an engram cell ensemble.

The systematic dissection of the molecular mechanisms involved in synaptic plasticity has revealed that the cascade of events underlying the plastic changes requires two distinct phases [9, 10]. In the encoding phase, also known as early long-term potentiation (E-LTP), an increase in intracellular Ca^{2+} concentration mediated by post-synaptic NMDA receptors elicits a change in synaptic weight by increasing the insertion and

the conductance of AMPA receptors [11]. The dendritic spines that support the post-synaptic machinery rapidly increase in number [12]. In a second phase lasting a few hours after the initial encoding period, the increased synaptic weight is maintained by a protein synthesis-dependent process known as cellular consolidation, during which the steady state synthesis of AMPA receptors is shifted to a higher level. This second phase is known as late LTP (L-LTP) [9, 10] and is sensitive to protein synthesis inhibitors (PSI).

To date, memory storage has mainly been investigated by pharmacological or molecular manipulation and by correlating synaptic changes with the strength of memory recall. Only recently has it become possible to specifically tag cells activated by learning. The demonstration that these cells are part of a memory engram ensemble was provided by a series of "optogenetic" experiments where a learning-induced tagging strategy was employed to express channelrhodopsin [13] in a small population of learning-activated cells [14, 15]. The opsin allowed for the artificial light-induced reactivation of the cellular population labeled during learning and resulted in memory retrieval. The same tagging strategy also verified the reactivation of tagged cells upon presentation of retrieval cues.

Tagging "engram" cells offers a straightforward opportunity to investigate the nature of the persistent changes that occurred in these cells in response to learning. In a recent study [16], "engram cells" were compared to "non engram cells" (non-tagged cells) by ex vivo patch clamp recordings after contextual fear conditioning (CFC). Engram cells displayed changes in synaptic weight typical of LTP such as high current amplitude, insertion of AMPA receptors, high spontaneous excitatory post-synaptic current frequency and amplitude, and increased dendritic spine density. These changes were blocked by the systemic injection of PSI specifically within the consolidation window. Therefore, it is now clear that cells recruited by learning display synaptic changes typical of LTP and are reactivated by retrieval cues, and their reactivation can elicit memory recall. Remarkably, however, protein synthesis-dependent L-LTP seems to be dispensable for memory storage because direct optogenetic activation of the engram cells in PSI-injected mice elicited full memory recall under a variety of conditions.

If L-LTP is dispensable for memory storage, what mechanism is responsible?

An integral memory engram may consist of preferential connectivity between engram cell ensembles distributed across multiple brain regions. In the same report [16] it was shown ex vivo that engram cells from the dentate gyrus established preferential connections with engram cells in the downstream hippocampal CA3 region in a feedforward excitatory engram cell circuit. Remarkably, this preferential connectivity was maintained in mice rendered amnesic by treatment with PSI within the consolidation window, suggesting that memory storage may survive retrograde amnesia in the form of a neural connectivity pattern. Indeed, optogenetic stimulation of DG engram cells in vivo elicited similar cellular reactivation patterns not only in the CA3 region but also in the amygdala for both control and amnesic groups, thus confirming the persistence of engram cell connectivity. These observations support the concept of preferential connectivity of engram cell ensembles distributed across multiple brain regions, which is established during learning and persists despite disruption of consolidation and thereby provides a lasting substrate for memory storage. These data also suggest that the synaptic potentiation observed in consolidated engram cells is necessary for memory retrievability and not for storage [17]. While regulation of synaptic weight provides a scalar quantity to control information retrieval, synaptic connectivity holds the information specificity. This is because synapses that are activated during the encoding stage will dictate the eventual pattern of cellular connectivity of the upstream and downstream engram cell ensembles. This notion is compatible with the broad view that synapses are the basic units of information storage (see Bonhoeffer, this Forum).

How would the specific connectivity pattern between engram cell ensembles be formed by specific learning?

Neural connections are formed during development and certain circuits hold the innate capability to elicit complex behavioral reactions in response to specific perceptual cues [18]. However, this does not seem to be the case in the hippocampal formation because inactivation of the downstream CA1 region before CFC results in anterograde amnesia which cannot be bypassed by direct optogenetic stimulation of DG engram cells [16]. Thus, the memory circuit is not configured under anterograde amnesic conditions and is not, therefore, genetically determined but requires hippocampal activity during memory encoding. As reported by Ryan et al. [16], learning-induced changes in connectivity patterns are insensitive to PSI. So is E-LTP [9, 10] and this early phase of plasticity may provide a framework to investigate the formation of new connections. For instance, blocking NMDA receptor function should impair the emergence of learning-induced connectivity patterns.

During the induction of LTP, existing connections can be potentiated [19] but new connections can also emerge [20]. A hypothetical way this might happen is through the activation of silent synaptic connections [21]. These synapses expressing only NMDA receptors and not AMPA receptors can become unsilenced through AMPA receptor insertion, a mechanism that could, in principle,

support the formation of learning-induced changes in engram cell connectivity. Another possibility is that local dendritic protein synthesis contributes to the rapid synapse formation on engram cells, independently of its role in synaptic potentiation (see Martin, this Forum).

What then maintains the learning-induced engram cell connectivity that is initiated during encoding?

Although learning-induced synaptic potentiation would be suppressed by PSI, the new connectivity pattern could persist through unsilenced synaptic connections of basal unpotentiated strength (Fig. 1). Consistent with this perspective, it has been recently shown that optogenetically induced long-term depression (LTD) of amygdala cells impaired existing conditioned fear responses but subsequent optogenetically induced LTP of the same cells could restore optogenetic cue-evoked recall of the fear memory [22].

The ability to tag cells activated by learning has opened up new horizons in the investigation of memory

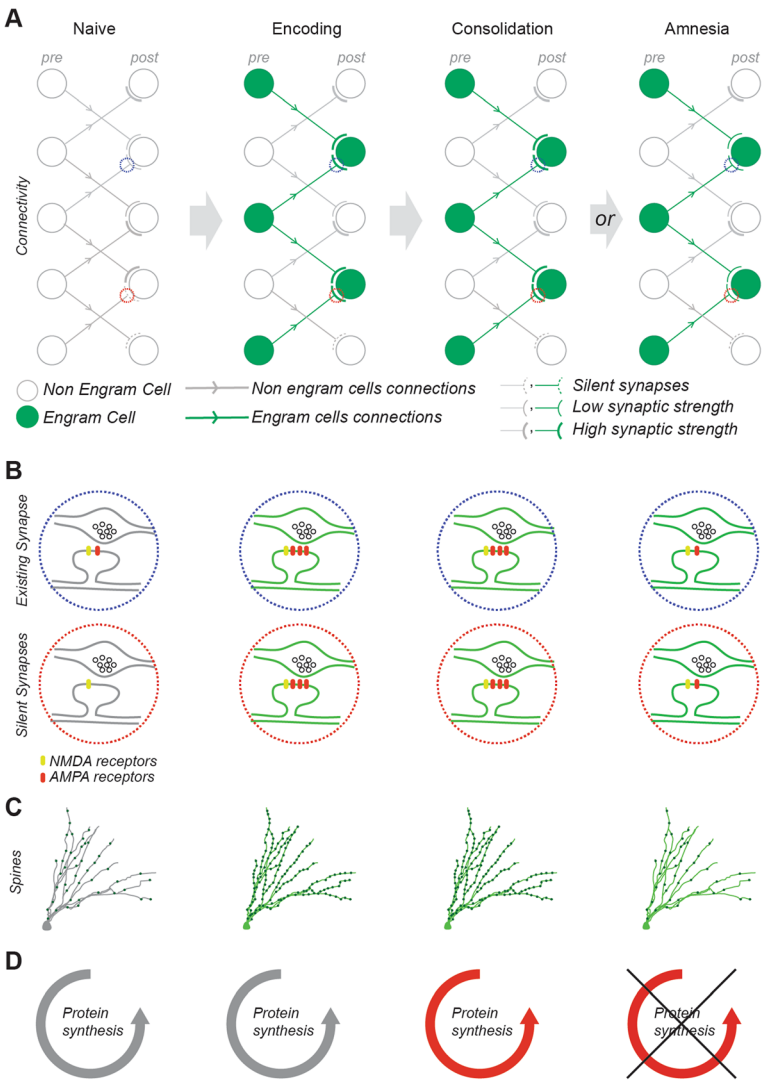

Fig. 1. Synaptic connectivity between engram cells as a mechanism for memory storage. **a** Cellular connectivity in a feedforward excitatory circuit, **b** synaptic configuration, **c** dendritic spine density, and **d** protein synthesis state, shown in a naïve circuit, a circuit during encoding, a circuit after consolidation, or a circuit in an amnesic condition. Engram circuit, cells, and synapses are displayed in *green*, non-engram in *gray*. In the naïve state, the circuit displays a variety of synaptic patterns, including strong (*thick gray lines*) and weak synapses (*thin gray lines*) as well as silent synapses (*dotted lines*) exclusively expressing NMDA receptors. During encoding, a network of engram cells is recruited. The preferential connection between engram cells occurs either by potentiation of existing connections (*blue dotted circles*) or by unsilencing synapses (*red dotted circles*). A spine density increase supports the synaptic changes. During consolidation, the steady state synthesis of AMPA receptors is shifted to a higher level and the disruption of consolidation with protein synthesis inhibitors (PSI) results in retrograde amnesia. However, during PSI-induced amnesia, memory storage persists within an engram-specific set of weak synaptic connections

by revealing the role of the engram-specific connectivity in the storage of information.

Spines and synapses as basic elements of memory storage

Tobias Bonhoeffer

In his seminal work, Donald Hebb [1] proposed that the basic mechanism by which memories are stored in the brain is the enhancement of synaptic strength and, in connection with that, morphological changes of the respective synaptic contacts. In other words he proposed that synapses and not cells are the basic building blocks of memory, from a theoretical perspective a reasonable suggestion as there are approximately 10,000–100,000 times more synapses in the brain than neurons.

By now it is well established that morphological changes at the synaptic level occur in conjunction with stimuli that are thought to mimic learning events. In vitro experiments [12, 23] have shown that long-term potentiation results in the addition of dendritic spines, tiny protrusions which harbor synaptic contacts. Tens of thousands of these spines decorate the dendrites of most excitatory cells in the hippocampus and the neocortex. And indeed, further studies showed that spines not only come and go but also change their shape during putative learning events [19], a suggestion that had been put forward in a purely theoretical paper by Francis Crick [24]. So, it is well established that spines emerge, disappear, and change with cellular events thought to underlie learning processes. But is this merely a correlation or are there ways towards showing that these events really lie at the basis of learning and memory storage in the brain? Recent experiments have made substantial progress in this respect.

The first study that made a clear case that spines are important for the long-term storage of information was done in the visual cortex of mice [25]. In the visual cortex it is well known that synaptic connections are established or modified with changes in visual experience, like the temporary closure of one eye. These plastic changes are often used as a proxy for what happens during memory formation since they share key features: it is, for instance, a universally accepted fact in memory research that information that has been acquired early in life can be learned much more easily a second time, even if it had been "completely forgotten" in the meantime. This effect has been called "savings" [26] and is a hallmark of most memory processes. It has been shown that the same effect occurs in the visual system [27]. Mice were monocularly deprived for a couple of days early in life so that the visual system adapted to this change of the visual environment. Subsequently, animals were subjected to normal vision again so that their visual cortex reverted to normal function. If monocular deprivation was then performed a second time, much later in life, when normally this procedure has only a very limited effect (if any), substantial adaptation still takes place because of the early experience that the animal has had. Importantly, this savings effect could be related to new spines that emerged during the first plasticity episode and persisted [25]. The fact that there was no growth of additional spines during the second plasticity period, while the functional adaptation occurred much faster and more reliably, suggests that the persistent spines facilitate the second adaptation [25]. Therefore, these spines serve to "remember" the previous sensory experiences the animals had. Two subsequent studies [28, 29] further bolstered the case by showing that also in the motor cortex the generation of new spines forms the basis of learning motor tasks of different sorts. Interestingly, in one of these studies [28] it was also found that relearning a task occurred faster and did not involve the generation of new spines, again arguing for persistent spines "memorizing" specific motor tasks. Furthermore, this study demonstrated that learning different tasks involves different sets of spines, providing a strong argument for spines and not cells being the relevant entity for information storage in the brain.

These three papers were among the first to make a strong case for a causal relationship between new (or changing) spines and learning or information storage in the brain. Subsequently, a number of studies further strengthened this hypothesis. Some of them used fear conditioning to show that also in this paradigm learning is paralleled by structural changes: fear extinction and fear conditioning are marked by the generation or removal of spines in the frontal association cortex [30] and the auditory cortex [31]. One particularly interesting finding in this context is that extinction induces appearance of spines that were eliminated upon the original fear conditioning to the same stimulus but not to a distinct conditioned stimulus, suggesting that the spines are again specifically associated with extinction of one specific association [30]. Interestingly, also in a completely different animal model—song learning in zebra finches—it was shown that new spines are generated in the forebrain nucleus HVC when an animal learns a new song from a tutor [32].

Finally, what about the experiment that has long been on the agenda [33], namely to specifically ablate spines that have been generated during learning? If the above interpretations are true, spine ablation should lead to forgetting of the information that was learned when the new spines were generated. First important strides in that direction have been made in a recent experiment by the group of Haruo Kasai [34], who specifically labeled spines that were generated at a particular time window immediately after learning. When these spines were later

ablated or at least reduced in size, the animal indeed forgot the previously learned information. The learning paradigm is so far relatively simple (rotarod learning) but it provides a very nice indication that the generation of new spines or their enlargement is truly causal at least in some forms of learning.

Taken together, there is now considerable evidence from different species as well as from different learning paradigms that spines, and thus synapses, change when an animal learns. Furthermore, there are convincing indications that the maintenance of previously established structural connections on the level of dendritic spines explains the memory phenomenon of savings. Finally, if spines are ablated, an animal forgets what it has learned through the addition of new or stronger spine synapses. All of these experiments seem to point strongly towards the notion that spines or synapses (and not entire cells) may be the smallest unit of memory storage in the brain and it may, therefore, be most appropriate to say that the "engram" of a memory is laid down in the set of spines or synapses that are changed when specific information is stored. This is of course not to say that engrams are not visible on the level of single cells (see preceding contribution to this Forum by Pignatelli, Ryan, and Tonegawa); after all, the activity of cells is determined by the complement of their synapses. Yet, the finest resolution of the engram may only become apparent if one truly considers everything on the basis of the pattern of synapses or spines which are changed during a particular memory event.

A cell biologist's view of memory: revisiting the neuron doctrine

Kelsey C. Martin

Over a century ago, the anatomist Ramon y Cajal used the Golgi staining method to visualize individual cells in the brain. He observed that the brain was composed of discrete cells rather than of a "reticular network" of interconnected cells (as was commonly believed at the time). Cajal's observations provided critical support for the neuron doctrine, which postulates that the neuron is the central unit of the brain. At the same time, his drawings revealed the beautiful complexity, polarity, and compartmentalization of neurons: cell bodies elaborating axonal and dendritic processes, forming up to thousands of synapses with one another. With a remarkable amount of prescience, Ramon y Cajal also speculated that memories were stored as increases in the numbers of connections between neurons. This idea forms the basis of learning-related synaptic plasticity—the idea that memories are stored as changes in the number and strength of synapses between neurons—a framework that has endured as a model for understanding the biology of memory.

Studies of memory in rodents and goldfish performed in the 1960s and 1970s demonstrated that long-term memory required protein synthesis whereas short-term memory did not [35]. Subsequent studies of learning-related plasticity in organisms ranging from *Aplysia* sensory-motor synapses to rodent hippocampal synapses similarly demonstrated that long-lasting forms of plasticity can be differentiated from short-term plasticity by their dependence on RNA and protein synthesis [36]. Molecular biological approaches led to the identification of many genes that contribute to long-term plasticity and memory and to the elucidation of specific patterns of neuronal activity and specific signaling pathways that trigger changes in RNA and protein synthesis within neurons. These findings gave rise to the idea that activity-dependent changes in the neuronal transcriptome and proteome mediate and/or maintain the changes in neuronal structure and physiology that result in persistent changes in synaptic strength.

Initially, studies of gene expression underlying memory focused on activity-dependent changes in transcription in the nucleus. The discovery of immediate early genes, such as c-fos, arc, and zif268, that were induced during memory formation implied that the neuron was the unit of long-term plasticity and memory [37]. Immediate early genes are now widely used to map neurons involved in memory formation, in line with the idea that memories are encoded within networks of discrete neurons in the brain.

In contrast to this neuron-centric view of memory formation, studies of learning-related plasticity revealed that plasticity was synapse-specific, that is, it could occur at some but not all synapses made by an individual neuron [38]. This finding raised questions about how the products of gene expression, synthesized in the nucleus, could be targeted to alter structure and function at subsets of synapses within a single, highly polarized and compartmentalized neuron. One solution to this question came from findings that mRNAs localized to distal dendrites and synapses [39], where their translation could be regulated by activity. These findings included detection of polyribosomes at the base of synapses as well as the identification of a subset of mRNAs that localized to distal dendrites. Studies from several labs have identified hundreds to thousands of dendritically localized mRNAs [40–42] translation of which could alter the structure and function of synapses, thereby making the synapse (or neighborhood of synapses), rather than the entire neuron, the unit of plasticity.

Local translation at synapses has been shown to regulate translation in a synapse-specific manner [43, 44] and inhibiting local translation at synapses in a variety of in vitro preparations has been shown to block long-term learning-related plasticity [45, 46]. In one of these

preparations, the *Aplysia* sensory-motor culture system, we directly tested the relationship between transcriptional regulation in the nucleus and translational regulation at the synapse during synaptic plasticity and found that stimulus-induced newly transcribed localized mRNAs were delivered throughout the neuron but were only translated at locally stimulated synapses [47]. The implication of this finding is that activity-dependent transcription sets the entire neuronal arbor in a state of readiness to respond to local cues via regulated translation of localized mRNAs. From the perspective of activity-dependent gene regulation, this idea shifts the focus from the neuron as the unit of plasticity to the synapse (or neighborhoods of synapses). In so doing, it underscores the need to refine the current neuron-based maps of memories by developing synaptic maps of memory in the brain (Fig. 2).

The focus on the synapse as the unit of plasticity calls into question aspects of the neuron doctrine. Thus, while the neuron doctrine assumes that neurons are separate, autonomous units, cell biological studies of synapses indicate that all components of the synapse are intimately interconnected, including not only the pre- and post-synaptic compartments but also glial processes. For example, in one study of local translation at *Aplysia* sensory-motor synapses, we found stimulus-induced local translation of a reporter depended on trans-synaptic signals from the post-synaptic motor neuron compartment to the presynaptic sensory neuron compartment [44]. Taking the idea of non-cell autonomy to an extreme, recent studies have reported that neurons and/or glia can transfer mRNAs and microRNAs to neighboring neurons and/or glia [48]. This finding raises the provocative idea that gene expression can be regulated by transfer of genetic information from cell to cell. As such, the idea of "local" translation serving to alter the structure and function of synapses encoding a memory suggests that "synaptic maps" of memory are not encoded by discrete synaptic compartments of individual cells but rather by complex fluid synaptic neighborhoods. These neighborhoods include not only the products of gene expression that are made in the nucleus of the neuron the synapse belongs to but also signals (including RNAs) from neighboring neurons and glia.

To add an additional layer of complexity onto this view of memory, single cell RNA sequencing experiments have uncovered remarkable complexity in the nerve cells and glia within the brain [49]. These findings indicate that synaptic neighborhoods are not just comprised of common modules of pre-synaptic, post-synaptic, and glial components but that they also exist in a multitude of distinct flavors or "ethnicities" as neighborhoods. A recent electron microscopic reconstruction of a small volume of mouse neocortex revealed that the formation of synapses between neurons is more dependent on cell identity than on proximity [50]. The diversity of cell identities, in combination with the idea that cell identity drives synapse formation, indicates that generating a synaptic map of memory will require understanding the distinct identities of the participating cells as well as the details of their cell-to-cell interactions.

As a cell biologist interested in understanding memory, the challenges moving forward include identifying conserved local processes that persistently alter synaptic function and developing methods to manipulate these processes in order to test their function in the formation and storage of memory. Possibilities include local mechanisms of translational regulation at synapses, trans-

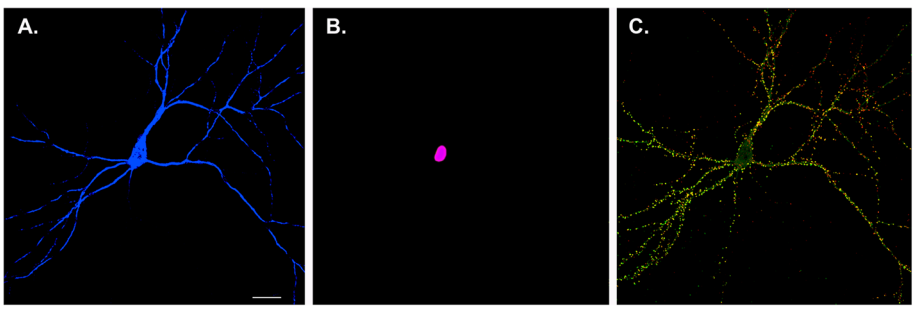

Fig. 2. Neuron versus synaptic maps of memory. The Golgi method used by Ramon y Cajal at the turn of the 19th century revealed that the brain consisted of individual nerve cells, leading to the formulation of the neuron doctrine. In modern neurobiology, expression of soluble fluorescent proteins allows visualization of individual neurons in the brain or, as shown here, in a hippocampal pyramidal neuron in dissociated culture (*blue*) (**a**). Identification of immediate early genes, such as cFos, provides a means of labeling the nuclei of individual neurons that are activated to undergo transcription following neuronal activity (*violet*) (**b**). This provides a neuron-level map of activity. However, each neuron forms thousands of synapses, shown in **c** by labeling a single neuron with presynaptic (*green*) and postsynaptic (*red*) markers (*yellow* where the pre- and post-synaptic elements are adjacent to one another). Note that this neuron is connected to other neurons in the culture that are not shown. Developing a synaptic rather than a neuron-wide map of memory requires obtaining activity-dependent markers that label the activated synapses rather than nuclei. Understanding synaptic maps will not only require understanding the identity of individual neurons but also the details of their cell-to-cell interactions

synaptic signaling pathways (including the transfer of RNAs via extracellular vesicles), interactions between synaptic cell-adhesion molecules, and even extracellular matrix dynamics. As an example of the latter, Roger Tsien has proposed that memories may be stored in the pattern of holes formed within the perineuronal net, a specialized extracellular matrix structure that is formed at the end of critical periods in the brain [51]. Taken together, recent lessons learned suggest that elucidation of these local processes requires consideration of the synaptic compartment as a local environment rather than as a collection of separate and autonomous membrane bound compartments. While morphology, from Golgi stains to electron microscopy, emphasizes the boundaries between cells in the brain, molecular cell biological studies uncover a fundamental role for local cell–cell interactions and interconnections in the encoding of memories.

Memory as a functional consequence of epigenetic priming in engram neurons

Andrii Rudenko and Li-Huei Tsai

Memory formation, storage, and recall constitute the essence of human nature. The search for the mechanisms underlying learning and memory has revealed the importance of a number of molecular and cellular processes, such as activity-dependent gene expression, intracellular signaling cascades, and synaptic plasticity [52, 53]. The long-lasting attempts to characterize memory localization recently resulted in identification of specific neuronal populations—so-called engrams—that provide a physical location for the storage and retrieval of memory traces [14, 15, 54, 55]. Despite discovery of the engram cells, molecular mechanisms of memory storage remain unclear. We propose that epigenetic alterations taking place in these cells may represent a critical process involved in the long-term retention of memory traces.

One well-studied example of such alterations is histone acetylation, a covalent mark of active chromatin. Mutations in CBP, a gene product necessary for the acetylation of multiple memory genes, result in severe intellectual disability in humans as well as in mice [56–58]. Conversely, histone deacetylase inhibitors (HDACi) were shown to restore histone acetylation and ameliorate cognitive deficits in a CBP-deficient mouse model [56, 57]. Moreover, HDACi have been found to ameliorate memory deficits in mouse models of Alzheimer's disease [59, 60]. In addition to histone acetylation, several other epigenetic mechanisms, including DNA methylation and hydroximethylation, have also been demonstrated to regulate memory function [61, 62].

While inhibiting HDACs was found to be effective in enhancing synaptic plasticity and memory, such inhibition per se, in the absence of neural stimulation, produced very limited results [63, 64]. Thus, HDAC inhibition appears to convey its effects on learning and memory via facilitating gene expression elicited by neural activity, a phenomenon known as epigenetic priming [65, 66].

As discussed earlier in this Forum by Pignatelli, Ryan, and Tonegawa, a recent study by Ryan et al. [16] has elegantly demonstrated that inhibiting protein synthesis during the memory consolidation window does not disrupt memory retrieval by means of engram activation. This exciting observation suggests that while augmented synaptic strength may be critical for memory encoding, some other mechanisms, potentially involving epigenomic modifications in engram neurons, appear to be necessary for memory trace storage. The recent discovery that long-term memory can be re-instated following erasure of its synaptic expression strongly supports this idea [67]. We propose that, mechanistically, the engram cells are marked, or tagged, not only synaptically [68] but also at the epigenetic level, be it histone acetylation, methylation, DNA methylation, or Topoisomerase IIβ-dependent topological changes of the DNA/chromatin, as recently suggested by our work [62, 69]. Specifically, the initial phase of memory formation would cause changes in the epigenetic state of the engram cells through a priming event which may be protein synthesis-independent (for example, epigenetic modifications to make specific genomic regions poised for efficient transcriptional activation). Such changes may also lead to long-lasting alterations in chromatin structure and function underlying the memory consolidation process. Finally, memory retrieval would signal the engram cells potentiating initial epigenetic priming, including molecular events such as generation of DNA breaks within the promoter areas of early response genes such as *c-Fos*, *Npas4*, *Nr4a1*, and *Egr1* [69], triggering expression of the primed genes leading to protein synthesis and increases in the number and strength of the synapses. Such a chain of events may explain why, even after considerable neurodegeneration, HDAC inhibition coupled with behavioral training is capable of reinstating learning and retrieval of long-term, and even remote, memory [59, 70]. This scenario may be possible if engram cells, epigenetically primed by the initial learning experience and capable of re-engaging in the chain of molecular events leading to memory retrieval, still remain in the brain after neurodegeneration.

We should note that in these early days of functional memory engram investigation, we still do not have satisfactory answers to many important questions. For example, the exact molecular and structural features of engram-containing networks, or potential mechanisms that might allow participation of a specific neuron in different engram ensembles, currently remain unknown. Moreover, although there is accumulating evidence of

the epigenetic marks/tags that would prime engram cells for an efficient transcriptional response, the exact nature of those marks remains unclear. Deciphering such priming signatures will help us immensely in understanding the mechanistic basis of memory processing.

Memory mechanisms: LTP and LTD in partnership, not merely in opposition

Richard W. Tsien, Gord Fishell, and Caitlin Mullins

How memory is stored in the brain can be effectively queried by examining how this process is affected in neuropsychiatric conditions. To this end, many aspects of the emerging pathophysiology of autism spectrum disorders (ASD) may provide insight into the tuning of synaptic strength in memory [71]. In ASD and related intellectual disability (ID), gene discovery points to dysregulation of interrelated neuronal functions, including control of nuclear gene expression, local protein synthesis in dendrites, and excitation:inhibition (E:I) coordination. These functions are linked together in feedback loops involving electrical or chemical sensors, termed "homeostats". The feedback loop may malfunction as a result of disease-causing mutations in any of the components. Given the effects of these disorders on cognition, it is likely no accident that the same set of functions loom large in current thinking about memory. Indeed, consideration of ASD and other neuropsychiatric diseases provides fresh perspective on the basic underpinnings of memory. From this viewpoint, we offer some thoughts about the relationship between LTP and LTD and the way that information in the brain may be stored and retrieved.

In an intriguing study published in 2012, Bourne and Harris used serial section electron microscopy to compare dendrites receiving either theta burst LTP or control stimulation [72]. As expected for LTP [34, 73], they found single spines with increased postsynaptic area by 2 h. Surprisingly, however, this occurred concomitant with a remarkable reduction in the number of small spines, leaving the total postsynaptic area per unit dendritic length unchanged compared with control (Fig. 3a). The constancy of total postsynaptic area per unit dendritic length fits well with prevailing concepts about homeostasis and normalization, but it also raises provocative questions about the neurobiological mechanism and organization of memory.

Two previously proposed and rather different hypotheses considered here might explain the underlying basis

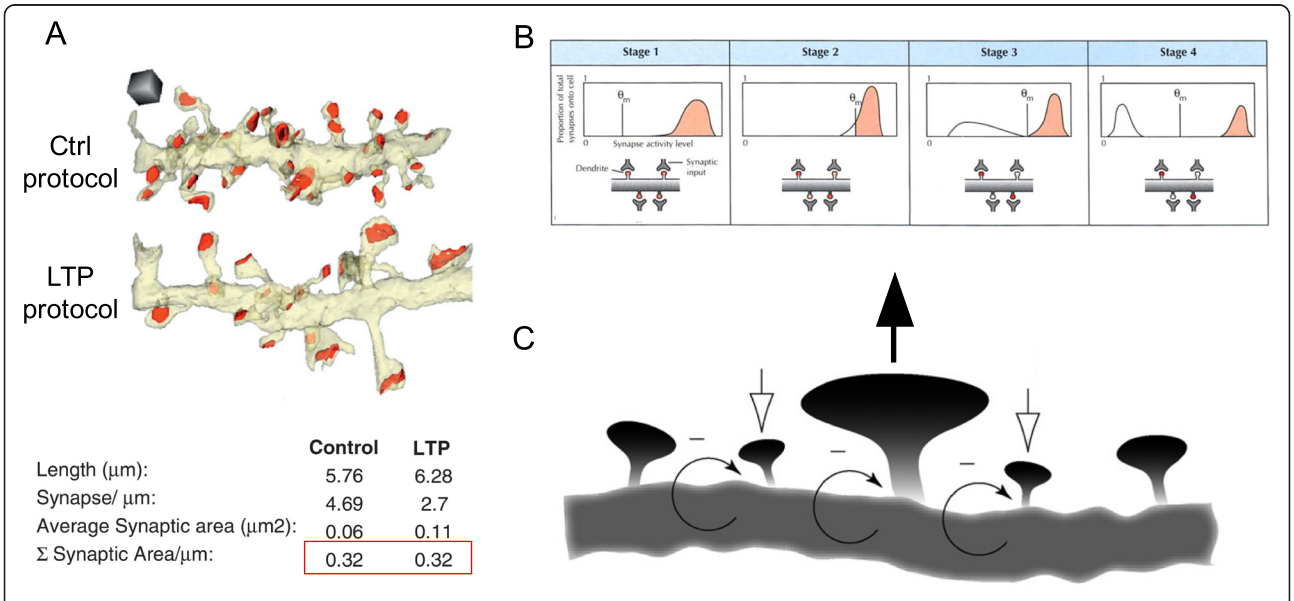

Fig. 3. Possible mechanisms of synaptic modification in memory storage. **a** Structural synaptic scaling is analyzed by serial section electron microscopy in hippocampal tissue under control and LTP (induced via theta burst stimulation) conditions. Control and LTP dendrites have equal postsynaptic areas (*red outline*) despite differences in synaptic density and size. Adapted from [72], with permission. **b** Representation of metaplasticity occurring, shifting the plasticity threshold (θ_m). The graphs on the *top row* depict the distribution of synaptic responses, *red shading* indicating LTP and *white shading* LTD. The four synapses illustrated (*bottom row*) reflect how the shifting of θ_m would impact the strength of individual synapses (intensity of *red shading* correlating to strength). Stage 1 depicts a saturating event, where all of the synaptic strengths have been excited to levels above θ_m. Stage 2 shows a metaplastic response to the activity levels reached in stage 1. In stage 2, θ_m has shifted such that some synapses are below the new threshold and weaken in stage 3. This changed θ_m leads to a new stable state, illustrated in stage 4. Reproduced from [75], with permission. **c** Synaptic potentiation at one spine (center, *upward-pointing black arrow* added for emphasis) is predicted to temporarily increase activity at adjacent spines. In response to the increased activity, homeostatic plasticity weakens the entire area (*negative feedback arrows*), with closely neighboring spines being disproportionately weakened (*downward-pointing white arrows*). The weakened spines allow the overall dendritic length to maintain a constant level of activity with the central spine still maintaining a level of potentiation. Adapted from [76], with permission

of Bourne and Harris' observations. In reviewing evidence for a "sliding threshold" concept [74], synaptic plasticity with flexible rules (metaplasticity), Deisseroth et al. [75] discussed a scheme that could fit with Bourne and Harris' results (Fig. 3b). If a stretch of dendrite receiving strong inputs undergoes LTP but then autoregulates the threshold dividing LTD and LTP, it would attain a new equilibrium that fractionates the synapses into stronger and weaker subpopulations (Fig. 3b). Also pertinent to Bourne and Harris' results, Rabinowitch and Segev [76] focused on lateral coordination of synaptic strength, invoking unknown mechanisms of local regulation on dendritic branches. In their hypothesis, LTP at spines receiving strong synaptic input is yoked together by a compensatory mechanism that weakens, or even eliminates, nearby neighbors (Fig. 3c).

Although these papers make no reference to each other, they converge on a shared view of synaptic plasticity, jointly supported by biological evidence and theoretical rationale: a synapse may undergo Hebbian strengthening or weakening as an individual entity but, over time, it can also behave as a connected entity, operating in coordination with other synapses in the same neuron or dendritic branch. Further, LTP and LTD can cooperate to redistribute synaptic weight. This notion differs from the traditional analogy between synapses and digital information storage devices, in which bits are stored and retrieved independently. On the other hand, coordination amongst multiple synapses, made by different inputs, provides benefits with regard to issues of normalization and signal-to-noise.

What can be said about the molecular mechanism(s) that might allow or even drive the coexistence of LTP and synaptic weakening in close proximity along a stretch of dendrite? This question has received much less attention than strengthening and weakening of the same synapses (see, for example, an elegant demonstration of LTP and LTD in direct opposition [22]). In the spirit of this Forum, we list here multiple possibilities for such lateral interaction:

1. Concentration of the excitatory neurotransmitter glutamate ([Glu]) must fall off with increasing distance from a strong input and could play some role in lateral interactions. Whereas NMDA receptors are essential for most forms of postsynaptically expressed LTP and are driven by high [Glu], lower levels of [Glu] would be sensed by the more sensitive metabotropic glutamate receptors (mGluR) at nearby synapses and could foster LTD mechanisms.
2. Different programs of local protein synthesis may be triggered by NMDARs and mGluRs and support LTP (e.g., increased synthesis of AMPA receptors) or LTD (e.g., upregulation of Arc). As we propose elsewhere [71], mutual inhibition between such translational programs could help enforce a sharp threshold dividing LTP and LTD, whereby local signals mediate LTP proximally and LTD at a distance. Interestingly, defects in either program can give rise to ASD.
3. βCaMKII (beta calcium/calmodulin-dependent protein kinase II) is well-suited to serve as a local sensor of activity-dependent rises in Ca^{2+} because of its high Ca^{2+}/CaM sensitivity. Hence, βCaMKII can also serve as an arbiter, dictating the decision between exo- and endocytosis of AMPARs to promote LTP/LTD. High [Ca^{2+}] activates βCaMKII, increasing AMPAR exocytosis [77]. In contrast, low [Ca^{2+}] leads to CaM-free, kinase-deactivated βCaMKII interacting with Arc, facilitating AMPAR endocytosis [78].
4. AMPA receptors can also be redistributed along the dendritic length by coordination of exocytosis of AMPARs and LTP at one site with endocytosis of AMPARs and LTD in flanking regions. A frank lateral transfer of AMPARs [79] could support a coupling of LTP/LTD at nearby dendritic spines.

Many studies on the cell biology of the dendrite take on different meaning if considered in this light. Also, an organizational principle of "robbing Peter to pay Paul" might engender marked strengthening of some synapses (rich getting richer) at the expense of others (poor getting poorer), thus contributing to empirical observations of a highly skewed distribution of synaptic weights [80–82]. It remains to be seen, however, whether the observations of Bourne and Harris are relevant to behavioral memory in vivo and whether the tradeoff of synaptic strength is predominantly a local, dendritic branch-based phenomenon as suggested by Rabinowitch and Segev [76] or also strongly dependent on regulation at the neuron-wide level [75, 83]. We have spoken little about the temporal dimension but the static snapshots in Fig. 3 are clearly shorthand for complex dendritic dynamics. Whatever the molecular/subcellular mechanism and dynamics, tradeoffs in synaptic strength will have a strong influence on the way that memory traces are stored and retrieved. As the debate continues about memory engrams and persistent changes at the level of synapses, synaptic neighborhoods, ensembles of cells, and even whole circuits, we would do well to consider redistribution in net synaptic strength as an underlying mechanism, rather than merely net increases or decreases. Perhaps we should modify silicon-based notions of memory units with independent read-write capabilities and embrace assemblies—not just "cell assemblies" [1, 17] but also "synaptic assemblies"—in their full spatiotemporal glory.

A role for adult-born neurons in pattern separation

J. Tiago Gonçalves, Matthew Shtrahman, Stephen T. Johnston, and Fred H. Gage

Memory involves the complex interplay between forming representations of novel objects or events and developing generalizations of similar experiences. Distinct instances of similar events must be discriminated—for example, being able to find your car at work despite parking in a different spot every day—but, at the same time, experiencing just a fragment of a familiar experience, such as a particular smell, can trigger specific memories from your childhood. The interplay between forming distinct memories and generalizing events is conceptualized to involve two separate processes: pattern separation and pattern completion.

The dentate gyrus (DG) is the information gateway of the hippocampal formation and as such plays a crucial role in hippocampal function, including the formation of episodic memories. Additionally, the DG is one of only two regions within the mammalian brain that generates new neurons throughout the life span of an individual in both rodents and humans [84–86]. There is increasing evidence that adult-born dentate granule cells (DGCs) are important for fine pattern separation of similar but distinct events [87, 88].

The DG as a pattern separator

The elegantly delineated anatomy of the hippocampus has long served as a substrate for theories about memory formation. It is grossly delineated into a series of interconnected loops within four major subregions. Specifically, the DG of the hippocampus receives excitatory input from the entorhinal cortex (EC) via the perforant path [89]. The DG then projects through the mossy fiber tract to form powerful synaptic connections with CA3 neurons, which in turn project to CA1, forming the classic trisynaptic pathway. In addition, the DG projects to and receives input from local inhibitory interneurons, most notably from the hilus.

In rodents, the DG contains approximately four- to fivefold more neurons than up- or downstream EC and CA3, respectively. Thus, input from relatively few cells is processed by a much larger neural network within the DG before generating a condensed output. However, only a small percentage of DGCs is activated in response to a given event [90, 91]. Based on these characteristics, modeling studies postulate that the DG is a competitive network that can function as a pattern separator by partially de-correlating inputs [3, 92]. One prediction from this theory is that the DG is critical for forming memories of events that are similar but not identical to each other. This prediction is supported by accumulating evidence from both high-resolution functional MRI studies in humans and studies of "behavioral pattern separation" in rodents [93, 94], where subjects discriminate between similar environments or sensory stimuli presented at different times.

What mechanistic role do adult-born DGCs play in behavioral pattern separation?

Although the gross anatomical connectivity of the DG suggests a role in pattern separation, the DG's ability to perform this function appears to be further enhanced via its ability to incorporate new neurons. Adult-born DGCs undergo a lengthy process of morphological and physiological maturation before they fully integrate into the local hippocampal network [95]. Each immature DGC enters a critical period of greater plasticity approximately 4 to 6 weeks after it is born. These immature DGCs exhibit greater excitability [96], receive less inhibition from local interneurons [97], are more broadly tuned to input stimuli [98], and exhibit greater synaptic plasticity [99] than mature cells. Therefore, immature adult-born DGCs may perform unique computational tasks critical for hippocampal function, in particular behavioral pattern separation [87, 100].

The physiological properties of immature neurons at the single-cell level, however, might yield counterintuitive predictions at the circuit level. While hyperexcitability and broad tuning of immature neurons may allow the hippocampus to encode novel stimuli, their broad tuning would also seem to suggest that a hippocampal circuit rich in immature neurons would fire more frequently and indiscriminately to various environmental inputs. Yet, this explanation appears to conflict with the role of the DG in pattern separation. Therefore, it has recently been proposed that, though hyperexcitable themselves, these immature neurons' key contributions could be to suppress overall DG activity, maintain network sparseness, and thereby decrease interference between memory representations [101–103] as illustrated in Fig. 4. Individual immature neurons may be more excitable and broadly tuned but it is hypothesized that these cells in turn activate inhibitory interneurons in the DG and hilus, resulting in greater inhibition of mature DGCs. Developing a unified picture of how single-cell physiological features combine to determine circuit-level responses and behavior presents a great challenge for future work.

Future steps for understanding the role of adult-born neurons in the DG

Previous efforts to link DG function to cellular and molecular mechanisms have been hindered by technical limitations. First, although extracellular recording of DGCs has been used to monitor the dynamics of neuronal firing patterns, sparse activity within the DG makes

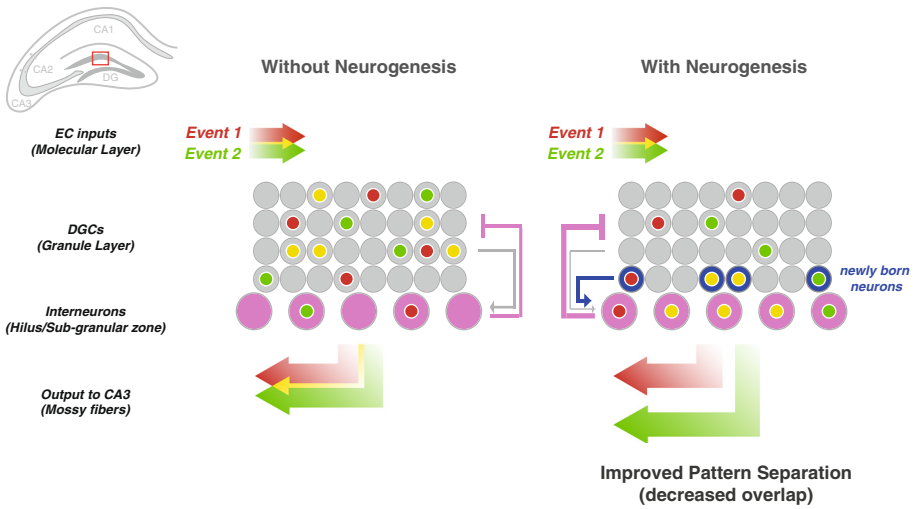

Fig. 4. Immature adult-born neurons improve pattern-separation in the DG by enhancing feedback inhibition. Two events are encoded in separate but partially overlapping populations of activated DGCs in the DG (*red* and *green*, with overlap in *yellow*). DGCs receive strong inhibitory inputs from interneurons (*purple*) in the hilus and sub-granular zone. It is hypothesized that hyperactive immature adult-born DGCs (*blue*) drive these interneurons, enhancing feedback inhibition from the hilus, which results in decreased overlap of activated DGCs and output to CA3, thereby improving pattern separation

it difficult to locate neurons, identify neuronal subtypes, and monitor the activity of a large population of DGCs [104]. Second, immunohistochemical analysis of immediate early gene expression, such as c-fos, can assess activity across a large population but only at limited time points, providing a limited snapshot of DG activity. Nevertheless, advances in in vivo recording techniques promise to eventually enable the monitoring of DG cells during behaviorally relevant tasks. In vivo imaging methods [105] in particular would be perfectly suited for recording DG activity—hundreds of cells can be monitored simultaneously and cellular subtypes identified through the use of genetic markers. Combined with modern techniques to manipulate activity in adult-born neurons, imaging large populations of neurons in vivo would permit testing the hypothesis that immature and mature DGCs work cooperatively to maintain the normal sparse network activity of the DG. These methods also have the potential to provide further insights into the mechanisms behind memory formation and recall, revolutionizing our understanding of the features encoded by both mature and immature DGCs and of how responsiveness to those features changes with learning.

Mechanisms for memorizing temporal sequence and interval

Mu-ming Poo and Yang Dan

The temporal sequence and interval of events are essential elements of episodic and procedural memories. Where and how sequence and interval information is stored in the brain remains a mystery. If modifications of synaptic connectivity are the cellular substrates for memory storage, then the challenge is to understand how distributed synaptic changes within neural circuits represent the sequence and interval of previously experienced sensory or motor events.

In his physiological postulate for perceptual memory, Hebb [1] proposed that reverberating activity generated by perceptual experience along distinct neuronal pathways could provide temporary storage of the experience. Repeated firing of a specific assembly of neurons in a particular temporal sequence could then serve to imprint the memory by modifying synaptic connections among the cells and re-activation of the assembly in this sequence represents recall of the memory.

The popular version of Hebb's postulate refers to synaptic modifications based on correlated pre- and postsynaptic firing ("cells that fire together wire together"), and it received experimental validation with the discovery of long-term potentiation (LTP) [5] and long-term depression (LTD) [106] induced by high- and low-frequency presynaptic stimulation, respectively—high-frequency stimulation results in postsynaptic spiking and thus LTP due to correlated activity, whereas low-frequency stimulation fails to do so, leading to LTD. The discovery of spike timing-dependent LTP and LTD [107, 108] led to further revision of Hebb's learning rule—the sequence of pre- and postsynaptic spiking, rather than simple coincidence of activity, is critical for determining whether the synapse is strengthened or weakened. The defined time windows for spike timing-dependent plasticity (STDP) [8, 109, 110] and its presence at many excitatory synapses [111] suggest that temporal information may be stored via STDP, and Hebb's assembly could be established by sequence-dependent synaptic

strengthening or weakening. In addition to the well-studied sequence replay in the hippocampus (see contribution by Long and Buzsáki in this Forum), this hypothesis was supported by a finding that repetitive visual stimulation with a unidirectional moving spot that evokes sequential spiking of the cortical neurons enhances their sequential firing in response to a flashed stimulus, in a manner that depends on the speed of the conditioning stimulus and activation of NMDA receptors in the visual cortex [112].

The time window for STDP, normally quite narrow (~20 ms) for LTP and wider and more variable (~20–100 ms) for LTD, also imposes a limit on the time intervals between pre- and postsynaptic spiking that can leave a long-term imprint at the synapse. Could the interval be extended via polysynaptic excitation within a network? A simple test of this idea was performed in a random synaptic network formed by dissociated hippocampal neurons in culture. Repetitive pair-pulse stimulation at a fixed interval was applied to a single input neuron and changes in the efficacy of polysynaptic connections within the network were measured. The result showed that intervals up to a few hundred milliseconds could lead to distributed long-term modifications (both LTP and LTD) of polysynaptic pathways within the network [113]. While this study provides proof of principle for encoding long intervals through polysynaptic delays, does the natural neuronal network in the brain contain serially connected groups of synchronously firing neurons (synfire chain) [114] to encode long sequences and temporal intervals? The finding of sequential firing of neurons in the premotor area HVC of songbirds during each song syllable (which lasts >100 ms [115]) indicates the existence of synfire chains in the brain, the formation of which underlies song learning [116]. Spike sequences lasting for several seconds have also been observed in the mammalian neocortex [117].

In addition to STDP in polysynaptic networks, memories of time intervals on the order of seconds are also likely to involve other mechanisms. In a study in zebrafish larvae, Sumbre et al. [118] applied a unidirectional moving visual stimulus repeatedly at a fixed temporal interval (several seconds) and recorded the population activity of tectal neurons with Ca^{2+} imaging. They found that following cessation of the visual stimulation, sequential firing of the tectal neurons resembling that evoked by the moving stimulus reappeared at the same time interval as the conditioning stimuli, and this rhythmic reappearance lasted for up to 20 s. This post-conditioning spontaneous rhythmic firing of tectal neurons reflects short-term memory of a specific rhythm with time intervals of seconds. Interestingly, since the tectal activity did not persist continuously through the several seconds of interval, it is unlikely mediated by reverberation of activity in the polysynaptic network. The underlying circuit mechanism and the location of memory storage in this case remain unknown.

Remembering the association between events separated by intervals ranging from seconds to tens of seconds has been referred to as temporal associative learning, and has been found in recent studies to depend critically on entorhinal cortex (EC)–hippocampal circuits [119–121]. Pathway-selective inhibition and optogenetic activation of the EC–hippocampal circuit showed that layer II "island cells" and layer III neurons of the EC control temporal associative learning [119, 120]; in particular, persistent activity of medial EC layer III neurons may play a key role [121]. Recent studies have also shown the existence of hippocampal "time cells" that fire at particular moments in a temporally structured experience [122–124], suggesting a function that parallels that of place cells in spatial memory. The sequential activation of such time cells in the hippocampus may reflect temporally structured inputs from the cortex and other brain regions or alternatively firing chain generated within local hippocampal circuits by repetitive sequential activity-induced strengthening of synaptic connections.

Theories and models of sequence learning and interval timing have been proposed [125–127] but very few studies have directly addressed the circuit and synaptic mechanisms [128, 129]. Since the cellular and synaptic building blocks of memory are increasingly well characterized and the technology for manipulating specific cells is becoming available (see other contributions to this Forum), the storage mechanisms for sequence and interval information are now amenable to fruitful exploration. Understanding these mechanisms is a pre-requisite for further studies of circuit mechanisms underlying higher cognitive functions involving complex temporal information processing such as human language, the ultimate challenge to neuroscience.

Hippocampal sharp wave-ripple: a repetitive mechanism to support single trial learning

John Long and György Buzsáki

Memories are not "imprinted" immediately but evolve over time. Memory has many forms and supportive brain mechanisms. While learning complex skills and habits, such as walking elegantly in high-heel shoes or riding a unicycle, may require tens to thousands of repetitions, consciously remembering episodic information, such as recalling one's first date, often requires only a single trial. The brain can achieve such a feat by deploying a mechanism that repeats segments of the original episode subconsciously hundreds to thousands of times after the experience. Such repetitions occur during non-attentive, off-line states of brain operation in the form of hippocampal sharp wave-ripples (SPW-Rs). SPW-Rs operate as a time-compressing mechanism, which can

transfer information from the hippocampus to numerous regions of the neocortex. SPW-Rs also serve as a preconscious "mixer" of existing knowledge and recently acquired information. Thus, acquiring episodic memory is a two-stage process, initiated by a rapid encoding mechanism during attentive waking and followed by a protracted consolidation process during "off-line" states of the brain [130].

SPW-Rs are self-generated hippocampal patterns

The SPW-R complex is the most synchronous and phylogenetically preserved pattern in the mammalian brain, associated with enhanced transient excitability in the hippocampus and its partner structures. These super-synchronous bursts arise when the release of subcortical neuromodulators within the hippocampus is decreased—for example, during consummatory behaviors and slow wave sleep. A SPW-R is a superposition of two events, the sharp wave-related population burst (SPW), which emerges in the strongly recurrent system of the CA2/3 regions, and the fast ripple oscillation, which is dominant in the CA1 output circuit of the hippocampus. The synchronous discharge of CA3 pyramidal cells excites primarily the mid-apical dendrites of the CA1 region and the inward currents brought about by this transient depolarization process (40–150 ms) manifest extracellularly as the local field potential SPW. The response of target circuits to the strong SPW-related depolarization is a fast oscillatory balancing act between principal cells and perisomatic inhibitory interneurons, resulting in the LFP ripple and the phase-locked discharge of sequentially active neurons [130]. It is this waking history-dependent, sequential firing of a large fraction of hippocampal cells, and consequent recruitment of neocortical neurons, that makes SPW-Rs a candidate biomarker for memory consolidation.

Compressed replay of experience during SPW-Rs serves memory

The restructuring of hippocampal–cortical networks through synaptic plasticity is necessary for the formation of new episodic memories. Neurons participating in SPW-R events are organized to fire sequentially and the orderly structure of these events reflects a temporally compressed version of the sequential neuronal firing patterns observed in the waking animal [131, 132] (Fig. 5; "replay"). For example, the sequences of "place cells" [133] in a novel environment are formed from a combination of relatively fast-firing and slow-firing groups of pyramidal neurons. Conspicuously, the former neurons exhibit relatively unchanging temporal dynamics while the latter are highly plastic. The greater plasticity of slow-firing pyramidal neurons is evidenced by their greater gain in place specificity during maze exploration and their increased SPW-R-related recruitment during sleep following waking experience [134]. These sequences are not confined to the hippocampus–entorhinal system; the SPW-R output also brings about sequential activations in neocortical circuits, such as the prefrontal cortex [135], leading to systems-level consolidation of the memory trace. Even more direct evidence for the role of SPW-R sequences in memory consolidation is provided by close-loop truncation of SPW-Rs. Selective elimination of the hundreds of SPW-R-assisted replays of recently learned sequences during post-learning sleep prevented rats from becoming proficient at a spatial-reference memory task [136]. This supports the hypothesis that single-trial learning is made possible by repeated off-line SPW-R replays of the wake-experienced episode.

Memory and planning: retrospective and prospective roles for SPW- R

A particularly striking feature of SPW-Rs is that the neuronal sequences contained in them can propagate both forward and backward (Fig. 5) relative to waking experience. Before the beginning of a journey upon a familiar maze, the upcoming sequences are preplayed during SPW-Rs in a forward manner; that is, prior to a run, the CA1 pyramidal cells fire in a sequence consistent with the upcoming trajectory of the animal in the maze. At the end of the journey, again, the same neurons are reactivated during SPW-Rs but now in a reversed direction as the hippocampus recapitulates the landmarks passed by the animal, though in a time-compressed manner. These findings support the hypothesis that forward replay events play a role in "planning" upcoming trajectories [137]. This hypothesis is further supported by several recent experiments that demonstrate that the routes chosen by the animal in two-dimensional environments or between maze corridors can be predicted by the spike sequence content of SPW-Rs [138]. The subconscious route-priming role of SPW-Rs is also supported by other experiments, which show that truncating SPW-Rs prior to a choice results in a spatial working memory deficit [139]. Because the neurons participating in SPW-Rs sequences are drawn from a diverse pool of log-scale firing rate distributed neurons, with varying coding, biophysical, circuit, and plasticity properties, these events can transit a vast array of preexisting and new information to downstream cortical partners [134].

To date, memory mechanisms in experimental animals are typically studied in the framework of spatial navigation [133]. However, it is important to emphasize that mechanisms of memory and planning have evolved from mechanisms of navigation in the physical world. Therefore, neuronal algorithms underlying navigation in real and mental space, as well as place memory and episodic memory, are fundamentally the same [140].

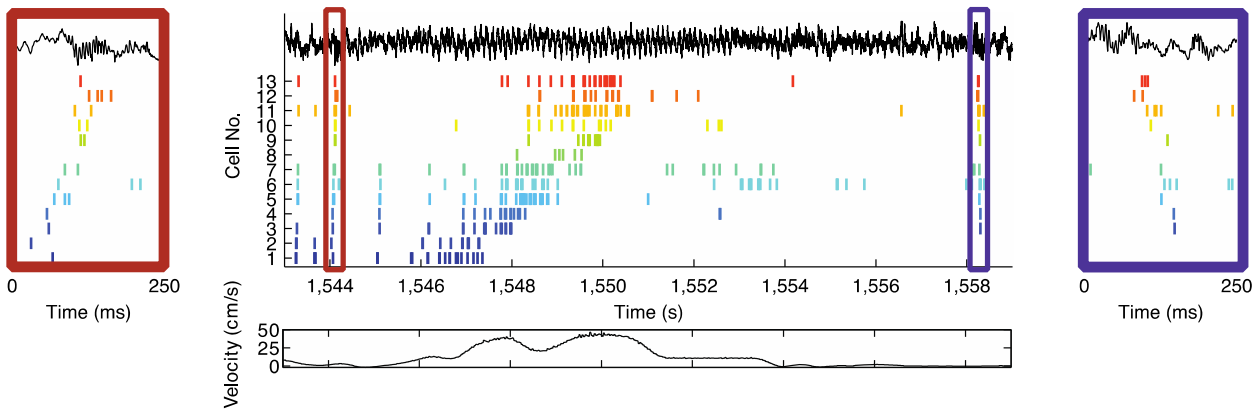

Fig. 5. Place cell sequences experienced during behavior (*middle panel*) are replayed in both forward (*left panel*) and reverse (*right panel*) direction during awake SPW-R. The rat is moving from left to right on a familiar track. Spike trains for place fields of 13 CA3 pyramidal cells (*color ticks*, spikes of individual neurons) on the track are shown before (forward replay; *left red box*), during (*middle*), and after (reverse replay; *right blue box*) a single traversal. The CA1 local field potential is shown on top (*black traces*) and the animal's velocity is shown below. Reproduced from [137]

Where is the study of Hebbian memory mechanisms going?

Charles F. Stevens

BMC Biology brought together some of the leaders in the learning and memory field to identify, from eight separate perspectives, some of the currently most important questions and approaches for understanding memory formation, consolidation, and retrieval. My job is to relate the current state of the field to how, in my opinion, it might evolve.

With rare, and highly valued, exceptions, a field develops organically from where it started and from the questions that grew out of each advance along the way. Although several of the contributions to this Forum relate key ideas from earlier eras (Cajal, Golgi, and Semon) to modern views, my starting point for the questions that drive learning and memory research will be Hebb's 1949 "firing - > wiring" proposal [1] for learning (cited in the introduction to this Forum and in four of the contributions).

Although Hebb's book was always well known to psychologists, it had essentially no impact on neurophysiology (as neuroscience was known in those days) for about a quarter of a century because the longest lasting form of synaptic plasticity known before 1973 (the date of Bliss and Lomo's LTP paper [5]) was post-tetanic potentiation (PTP) and this form of plasticity lasted, at most, only a few minutes. The only suggested brain mechanism for memory storage had been "reverberating circuits" and Von Neumann gave a compelling argument against the plausibility of this idea in his 1957 lectures at Yale on "The computer and the brain" [141]. Neurophysiologists were all very interested in the cellular basis of memory—everyone agreed it was a central problem—but no one had any idea how to study it.

As with any novel finding at odds with current knowledge and concepts, Bliss and Lomo's LTP paper [5] did not make an immediate splash. Indeed, during the next decade only a hand-full of researchers worked on LTP. But over the succeeding decades the study of LTP grew explosively to become a large and important sub-field of neuroscience, some would even say a preoccupation. As this Forum shows, we have learned an enormous amount about synaptic plasticity in the two-thirds of a century since Hebb's *The Organization of Behavior*. But where will we go now?

First, I need to confess that my record for predicting the future is abysmal: I have failed close to 100 % of the time. This time, however, I am trying a new strategy to see if I can move up from abysmal to, say, just terrible. This new approach is to see where the questions that drive our research have come from and then ask what we might have missed in asking these questions. Because of space constraints, I will focus on a single question: what might Hebbian learning be missing?

Although Behaviorism is pretty much dead [142], there is absolutely no question that reinforcement plays a key role in what behaviors an animal selects. And, as anyone who has experienced a traumatic event can tell you, the circumstances associated with the event are committed to an enduring memory (what were you doing when you heard about the 9/11/2001 terrorist attacks in the United States?). Of course, everyone is aware of this, yet the focus on Hebb's rule tends to neglect these other types of learning. Major exceptions to this are the climbing fibers in the cerebellum and the mossy fibers in the CA3 region of the hippocampus, where a single impulse or brief burst will fire the target neuron and is believed to potentiate the other synapses that are active at the same time. For both of these cases, Hebb's rule is sufficient to determine what needs to be learned.

So my specific prediction is that future scientists working on LTP/LTD (or STDP) will also include reward (positive or negative) related mechanisms in their investigations of synaptic plasticity at the molecular, cellular, circuit, and behavioral levels.

Where can we look to get guidance on wedding Hebb's rule to reinforcement learning? One of the simplest and best studied examples of alternative learning rules is the fruit fly olfactory system, where flies can learn to approach or avoid any odor if that odor is paired with reward (sugar water) or punishment (electric shock). A good example from Glenn Turner's laboratory [143] is an electrophysiological study showing how a specific dopamine neuron can decrease the synaptic strength of inputs into a specific mushroom body output neuron (MBON). The inputs into the MBON are synapses from 2000 mushroom body Kenyon cells and each odor activates a specific subpopulation of the Kenyon cells, about 100/2000. These 100 cells constitute a *tag* for that odor [144], a unique subpopulation of Kenyon cells whose firing stands in for the odor's combinatorial code generated by odorant receptor neurons in the fly's antennae. When the odor is paired with a shock, the specific dopamine neuron whose synapses overlap with the MBON's dendritic arbor and with the Kenyon cell's axonal arbor is activated. Firing of this dopamine neuron is what causes the Kenyon cell synapses to weaken and this change in synaptic strength is responsible for the avoidance of the odor associated with punishment.

Most scientists who study LTP/LTD/STDP use mammals as their experimental animals. It seems, however, that the dopamine system is, to a large degree, evolutionarily conserved even though the fly circuits are generally less complex than the corresponding ones in vertebrates. I am not aware of a review article that documents the insect/vertebrate parallels in the dopamine systems but the literature on the amygdala, a vertebrate center for valence learning, is vast [145] and can be compared to the large fly literature devoted to mushroom body learning and memory [146].

We can see over the next few years if my success for predicting future trends in science has improved.

The Pull of the Past: When Do Habits Persist Despite Conflict With Motives?

David T. Neal[1], Wendy Wood[1], Mengju Wu[2], and David Kurlander[3]

Abstract

To identify the factors that disrupt and maintain habit performance, two field experiments tested the conditions under which people eat out of habit, leading them to resist motivational influences. Habitual popcorn eaters at a cinema were minimally influenced by their hunger or how much they liked the food, and they ate equal amounts of stale and fresh popcorn. Yet, mechanisms of automaticity influenced habit performance: Participants ate out of habit, regardless of freshness, only when currently in the context associated with past performance (i.e., a cinema; Study 1) and only when eating in a way that allowed them to automatically execute the response cued by that context (i.e., eating with their dominant hand; Study 2). Across all conditions, participants with weaker cinema-popcorn-eating habits ate because of motivations such as liking for the popcorn. The findings reveal how habits resist conflicting motives and provide insight into promising mechanisms of habit change.

Keywords

attitudes, automatic processes, health, self-regulation

Received August 27, 2010; revision accepted April 10, 2011

Habits develop when people give a response repeatedly in a particular context and thereby form associations in memory between the response and recurring context cues. Theories of automaticity illuminate the cognitive mechanisms behind habits. When people have a strong habit, perception of recurring context cues activates the response in memory and may additionally deactivate alternative responses (Danner, Aarts, & de Vries, 2008; Neal, Labrecque, Wood, & Lally, 2011). For example, when habitual runners were subliminally primed with words relating to the contexts in which they ran (e.g., *gym, forest*), the act of running became strongly accessible in thought (Neal et al., 2011). Suggesting that this context cuing process may be minimally influenced by motivations, subliminally priming participants' personal goals for running did not make running habits more accessible.

Habits initially are likely to form through goal pursuit—as people repeatedly perform actions that yield desired outcomes. However, once habits have developed, they are performed with only limited influence from supporting motivations (Triandis, 1977, 1979). Nonetheless, experimental tests of how these mechanisms play out with real-world behaviors have not yet been provided. The present research provides these tests by independently manipulating motivational and contextual factors across two field experiments with a socially significant behavior, habitual eating.

The basic question in our experiments is: What disrupts habit performance? The design pitted negative attitudes toward stale food against established habits to eat in a given context. If people continue to perform habits despite this substantial conflicting motive, then habits are resistant to changes in attitudes and goals. Although habits may not be easily influenced by motives, their dependence on context cues should make them vulnerable to disruptions in automaticity. That is, habits should not be *activated* automatically outside of their typical performance context and should not be *executed* automatically when responses are performed in novel ways (e.g., using the nondominant hand). By manipulating the factors that do and do not control habits, we can test whether strong habits become responsive to current motivations when automaticity is disrupted.

Evidence of the Automaticity Guiding Habitual Behavior

Social psychological experiments have largely focused on types of automaticity that flexibly accommodate to current

goals and attitudes (Kruglanski et al., 2002). Yet, research in neuroscience, animal learning, and correlational studies of everyday behavior has focused primarily on cued actions that are not influenced by current motives (reviewed in Wood & Neal, 2007, 2009).

In neuroscience research on the brain systems activated during behavioral tasks, performance of stimulus–response habits is localized in the basal ganglia, especially the putamen, whereas control of goal-directed actions is localized in other brain regions, often involving the prefrontal cortex (Balleine & O'Doherty, 2010; Yin & Knowlton, 2006). Thus, habit formation involves neural shifts from "largely evaluation-driven circuits to those engaged in performance" (Graybiel, 2008, p. 362). Furthermore, the different brain systems controlling habits and goal-directed behavior often compete in guiding action such that activity associated with goal-directed control may be actively suppressed during performance of habitual behavior (Balleine & O'Doherty, 2010; Poldrack et al., 2001). Animal learning research also differentiates habits from goal-directed actions, primarily in terms of behavioral reactions to rewards. Specifically, extended training at a task such as lever pressing for a food reward produces habitual, continued responding to the lever cue even after the reward is devalued (e.g., the animal is sated, the food has been associated with a toxin; Dickinson & Balleine, 1995).

The minimal influence of motivations on habit performance also is a central finding of correlational studies of everyday behavior, including *behavior prediction* (Triandis, 1977) and *habit discontinuity* (Verplanken, Walker, Davis, & Jurasek, 2008). Across a range of everyday behaviors—from bus travel, to fast food consumption, to exercise—motivational factors (e.g., attitudes, intentions, self-concept, attitude accessibility) predicted future performance for nonhabitual behaviors but had limited predictive power for strong habits (Ouellette & Wood, 1998). Furthermore, consistent with the idea that habits are cognitively represented as context–response associations, habit strength had these effects only when habits were assessed from frequent performance in stable contexts—the specific conditions that enable the formation of habit associations in memory (Aldrich, Montgomery, & Wood, in press; Danner et al., 2008). Discontinuity studies that assess naturally occurring context changes find that participants continue to perform habits with minimal influence from goals, but only so long as they continue to live in the same context (Verplanken et al., 2008; Wood, Tam, & Witt, 2005). When participants move house to a new location without cues to habit performance, they apparently are freed to act on their goals.

The findings from neuroscience, animal learning, and correlational research on everyday behavior suggest that, once developed, habits are performed with limited influence from motivations. It may be that strong habits are directly brought to mind by the context cues (e.g., settings, preceding actions) associated with prior performance. Then, through ideomotor processes, people may act on the accessible behavior in mind (Bargh, 1994). According to this view, for example, a person's habit to snack on crackers at night may come to be directly cued by sitting in front of the TV, and changes in motivational states of hunger and liking for food may have little influence on how much the person eats.

Attitudes and Goals Flexibly Guide Behavior

The insensitivity of habit performance to current motives outlined in the preceding research might seem surprising to social psychologists given the field's focus on the flexible operation of attitudes and goals. Although strong goals and attitudes are known to have enduring influence, they usually guide responding in a given context depending on the expected outcomes of an action and the value placed on those outcomes (Eagly & Chaiken, 1993). Thus, people act on strong food preferences in a given context depending on what food is available and how tasty it is. Even *automatic goal pursuit*—in which goals are activated and guide responding outside of awareness—yields "not a static behavioral response, but an automated *strategy* for dealing with the environment" (Bargh & Barndollar, 1996, p. 461, italics in original). Similarly, automatically activated attitudes often are malleable and context dependent (Dijksterhuis, Smith, van Baaren, & Wigboldus, 2005).

The flexible influence of implicit goals and attitudes is evident in research that opposes implicit against explicit motives. For example, Macrae and Johnston's (1998) participants responded to implicit priming of a helping goal by offering assistance to someone in need, except when the implicit helping goal was inconsistent with their explicit goal of being on time. In other research, participants carried out implementation intentions to study—a form of automatic goal pursuit in which people plan to perform a particular response upon encountering a particular cue—only when they held the explicit goal of studying (Sheeran, Webb, & Gollwitzer, 2005). In an experiment related to our present focus on eating habits, implicit goals relevant to thirst increased the amount that participants drank during a beverage taste test, but only when they were thirsty (Strahan, Spencer, & Zanna, 2002). Nonetheless, conflicts between explicit and implicit goals are not always resolved in favor of explicit ones (Shah & Kruglanski, 2002). Instead, these dispositions combine in dynamic ways to shape responding in goal pursuit.

Habits contrast with the flexible pattern of responding characteristic of motives. Unlike automatic goals and attitudes, performance of strong habits may not be dynamically responsive to current motives. Thus, a strong habit to eat a particular food in a given context may be insensitive to current hunger levels or the palatability of the food.

The Present Research

To test the factors that can alter habit performance, we conducted two field experiments varying the conditions under which people consume popcorn at a movie cinema. Some participants in our research had strong habits to eat popcorn at the cinema (i.e., a history of frequent popcorn consumption in that setting), whereas others had weaker habits. We chose to study eating behavior in part because it is a significant social problem and in part because eating provides a strong test of the sensitivity of habits to changes in motivations. People believe that their eating behavior is largely a motivated activity in response to the way food tastes (e.g., Vartanian, Herman, & Wansink, 2008). Indeed, 17 of 22 participants in a pilot study provided "tastes good" or a close synonym when asked why they ate popcorn at the cinema. Thus, in the present experiments, we manipulated attitudes toward the food through its palatability. For some participants, the popcorn was fresh, whereas for others it was 7 days old and stale (adapted from Wansink & Kim, 2005).

To test the effects of changes in motivations, we first assessed whether participants with strong and weak habits evaluated the popcorn in the same way. It is possible that strong-habit participants would report more favorable attitudes even toward stale popcorn. By assessing attitudes toward the specific popcorn served and not toward popcorn in general, we evaluated the immediate, proximal attitude relevant to participants' eating. We also assessed participants' reported hunger and, in Study 2, their perceptions of social norms. Our second test of the susceptibility of habits to shifts in motivations involved assessing how much popcorn participants ate. Specifically, we evaluated whether participants with strong habits ate more of the liked, fresh popcorn than the disliked, stale popcorn and ate more when they were hungry.

Even if habits are not responsive to changes in motives, they should be disrupted by challenges to habit cuing. In Study 1, participants were tested either in the context relevant to their habit (watching movies in a cinema) or in a novel context (watching music videos in a conference room). We anticipated that habits would be automatically brought to mind only in the cinema context. In Study 2, all participants ate in the habit-related context of a cinema, and we manipulated whether they ate in their typical way (with their dominant hand) or in a novel way (using their nondominant hand). Using one's nondominant hand has been shown to impede the automatic, smooth performance of habitual responses (Sakai, Kitaguchi, & Hikosaka, 2003), presumably because it brings the action under intentional control. Thus, eating habits should be automatically executed only when eating with the dominant hand.

If habits resist changes in motives but can be disrupted by changes in automatic cuing, then we anticipate the following three-way interaction: Participants at the cinema with strong popcorn habits should be guided by the action in mind and eat similar amounts of fresh and stale popcorn. In contrast, participants with weak or moderate habits should eat more of the fresh popcorn that they like. Alternatively, when automatic cuing is disrupted by eating in a novel context or eating in a cinema but in a novel manner, then even strong-habit participants are likely to fall back on their attitudes and consume more fresh than stale popcorn.

Study 1

Method

Design and participants. Study 1 used a Context (cinema vs. meeting room) × Food Attitudes (fresh vs. stale) between-participants design. Habit strength for eating popcorn at the movies was an additional, continuous predictor. For the cinema context, 98 participants (57 males) were recruited immediately before the showing of a regularly scheduled feature film at a campus cinema. For the meeting room context, 60 participants (35 males) were recruited through flyers and participated in a campus meeting room near the cinema. Participants were paid $6 for completing the study.[1]

Procedure

Participants in the cinema setting were told that the study examined personality differences in movie interests and that they would rate a series of movie trailers. Sessions were conducted in groups of around 15. Before entering the theater, participants rated their current feelings (hunger, time since last meal, several filler items) and were given a 591-ml bottle of water and a box of popcorn. Participants were randomly assigned to receive popcorn that was either fresh (popped 1 hr before the session) or stale (popped 7 days before the session). Each box was discretely numbered so that it could be matched to participants' survey responses. Boxes were weighed before and after distribution on a digital scale, with initial amount averaging 61.73 g (SD = 6.74).

Participants entered the theater with their popcorn and water and, to reduce potential social influence, sat as far as possible from other participants. The lights immediately dimmed, and a series of six movie trailers for unreleased films was shown, totaling 15 min of viewing time. All popcorn boxes and water containers were collected immediately after the final trailer. Participants then moved to the cinema foyer and completed the survey, which, to maintain the cover story, first assessed their interest in seeing each film and then included a personality inventory and the liking and habit strength measures (see below).

Participants in the meeting room condition followed a similar procedure with one critical modification. The study was conducted in a campus meeting room and involved watching and rating music videos, a novel setting not associated

Table 1. Mean Liking of Popcorn Received in Studies 1 and 2 as a Function of Experimental Condition

	Fresh		Stale	
Habit cuing manipulation	*M*	*SD*	*M*	*SD*
Study 1				
Cinema	3.51	(0.93)	2.60	(1.16)
Meeting room	3.60	(0.96)	3.03	(0.89)
Study 2				
Eating with dominant hand	4.18	(1.42)	3.10	(1.42)
Eating with nondominant hand	4.50	(1.31)	2.72	(1.36)

Higher numbers reflect more positive ratings of the popcorn on a 7-point scale ranging from *very bad* (1) to *very good* (7).

with prior popcorn eating. A pilot test ($N = 22$) confirmed that the music videos were equivalent to the movie trailers in terms of their interest value and attentional involvement ($ts < 1$). Instead of rating their interest in watching each movie, participants rated their interest in owning each music video. All other aspects of the design were identical to the cinema setting (e.g., lighting levels, popcorn boxes, time since last major meal, number and visibility of other participants).

Hunger ratings. Before watching the videos, participants rated their current hunger on a 5-point scale (anchors *not at all* to *extremely*).

Ratings of popcorn attitude. On a 7-point scale, participants rated their liking for the popcorn they received (anchors *very bad* to *very good*).

Habit strength. On a 7-point scale, participants indicated how frequently in the past they ate popcorn in movie theaters (anchors *always* to *never*, reverse scored).

Results and Discussion

Our primary hypotheses were tested via regression models with the following predictors: context (cinema vs. meeting room), popcorn freshness (stale vs. fresh), habit strength to eat popcorn in theaters, and all two- and three-way interactions. Gender was a control variable in all analyses.

Reported attitudes and hunger. To establish that the experiment was constructed appropriately to test our hypotheses, we first used the regression model to predict participants' liking of the popcorn they received. As expected, the model yielded only a main effect of the freshness manipulation, $B = 0.54$, $t(141) = 1.98$, $SE = 0.27$, $p = .05$, establishing that fresh popcorn was liked significantly more than stale. Importantly, this effect was not qualified by any interactions with context or habit strength.[2] Mean liking of fresh popcorn was close to the scale midpoint ($M = 3.56$, $SD = 1.23$), and mean liking of stale popcorn was below the midpoint ($M = 2.72$, $SD = 0.91$), demonstrating that participants decidedly disliked the stale popcorn (see Table 1). No other differences in liking or in self-reported hunger emerged across conditions. Thus, participants in the meeting room had similar levels of hunger to those in the cinema, $t(144) = 1.57$, $SE = 0.16$, $p = .117$. Furthermore, the comparable ratings of popcorn in both contexts suggests that participants in the meeting room did not pay any closer attention to the popcorn than those at the cinema, $t(144) = 1.30$, $SE = 0.18$, $p = .194$.

Factors influencing performance of eating habits. The percentage of popcorn participants consumed was then analyzed with the regression model. Significant main effects emerged for gender (men ate more), $B = 14.37$, $t(142) = 3.32$, $SE = 4.32$, $p = .001$; context, $B = 27.20$, $t(142) = 4.53$, $SE = 6.00$, $p = .001$; and freshness, $B = 15.96$, $t(142) = 2.27$, $SE = 7.05$, $p = .025$. The latter two effects were qualified by the predicted three-way interaction between habit strength, context, and freshness, $B = 11.36$, $t(142) = 2.04$, $SE = 5.56$, $p = .043$, and no other effects were significant. To test whether strong-habit participants' eating was activated automatically in the cinema context with little regard for freshness, we calculated simple regression slopes between percent of popcorn consumed and freshness of the popcorn separately for participants with weak, moderate, and strong consumption habits in the cinema (Cohen, Cohen, West, & Aiken, 2003; see Figure 1).

In the cinema context, participants with weak habits—who infrequently ate popcorn at cinemas—ate significantly less popcorn in the stale than in the fresh conditions, $B = –30.03$, $t(90) = 4.28$, $SE = 7.01$, $p = .001$. Those with moderate popcorn eating habits also ate less stale than fresh popcorn, $B = –19.87$, $t(90) = 4.94$, $SE = 4.02$, $p = .001$. Importantly, as predicted, those with strong popcorn eating habits ate the same percentage of stale as fresh popcorn when located in the cinema environment, $B = –9.72$, $t(90) = 1.41$, $SE = 6.89$, $p = .162$.

In the meeting room context, an effect of freshness was evident at every level of habit strength. Specifically, people ate (at least marginally) less stale than fresh popcorn, whether they had weak habits, $B = –11.24$, $t(90) = 1.86$, $SE = 6.04$, $p = .074$; moderate habits, $B = –17.21$, $t(90) = 4.09$, $SE = 4.21$, $p = 0.001$; or strong habits, $B = –23.17$, $t(90) = 3.03$, $SE = 7.65$, $p = .001$. Critically, this pattern demonstrates that when tested in a novel environment, participants with strong popcorn consumption habits ate less stale than fresh popcorn.

Habit performance did not depend on motives. We conducted separate analyses to evaluate directly whether habit performance depended on participants' hunger and liking for the popcorn. To evaluate hunger as a moderator, we included this factor as a predictor in the model. Although hungrier participants ate marginally more in general, $B = 4.01$, $t(142) = 1.7$, $SE = 2.36$, $p = .092$, the critical interaction between hunger and habit strength was not significant ($t < 1$), suggesting that habit effects did not depend on this motive. Even more importantly, after including hunger and the Hunger × Habit Strength interaction, the predicted three-way interaction maintained between habit strength, context, and freshness, $B = 12.27$, $t(142) = 2.17$, $SE = 5.66$, $p = .032$.

Downloaded from psp.sagepub.com at UNIV OF ILLINOIS URBANA on October 19, 2014

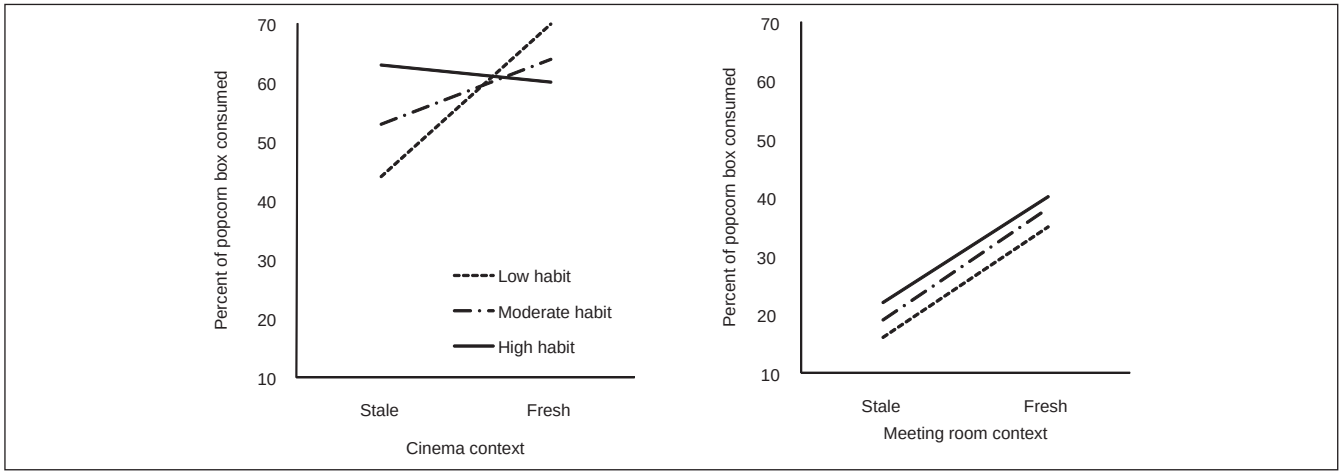

Figure 1. Percentage of popcorn eaten during 15 min of movie trailers in the cinema and 15 min of music videos in the meeting room (Study 1)

Simple slopes depict percent consumed of stale and fresh popcorn for those with strong (mean + 1 *SD*), moderate (mean), and weak (mean – 1 *SD*) habits for eating popcorn at cinemas.

We then conducted analyses evaluating liking as a moderator. Again, this motivation had a main effect, with participants eating more popcorn when they liked it more, $B = 8.32$, $t(142) = 3.95$, $SE = 2.11$, $p < .001$, but the interaction between liking and habit strength was not significant ($t < 1$), suggesting that habit effects did not depend on this attitude. Furthermore, the three-way interaction between habit strength, context, and freshness remained close to significant after including these effects in the model, $B = 9.69$, $t(142) = 1.80$, $SE = 5.35$, $p = .07$.

In general, the overall pattern suggests that habit performance resists shifts in attitudes but can be disrupted by shifts in habit cuing. It is important to note that strong-habit participants experienced the shift in motivation as a function of the food's freshness. They rated the fresh popcorn as more likable than the stale, and thus they did not value the popcorn more than those with weak habits. Because we assessed liking for the specific popcorn in the experiment and not popcorn in general, we evaluated the attitude toward the object most closely linked to consumption of this particular food. Although strong-habit participants experienced this motivational shift, their eating was not guided by it. That is, when in the cinema so that eating was activated automatically by the context, these participants consumed about 63% of the popcorn regardless of its palatability. Furthermore, tests of whether the habit effects depended on liking for the popcorn or current hunger revealed that these factors did not moderate the effects of habit strength on eating.

The eating behavior of strong-habit participants was, however, disrupted by features associated with automatic cuing. When in the meeting room watching movie videos, cinema-popcorn habits were not automatically activated, and strong-habit participants' behavior was brought under intentional control. Then, like the weak-habit participants in all conditions, they ate about half as much stale popcorn compared with fresh popcorn. Thus, participants' habitual eating was resistant to changes in motivational states but influenced by variations in habit automaticity.

Study 2

Study 2 replicated the test of insensitivity of habit performance to motivational states and tested an additional disruption of habit automaticity—whether the response could be repeated as in the past or had to be performed in a novel way. We anticipated that participants performing the response in a novel way would be unable to act automatically on any habitual response triggered by the cinema context. To test this idea, half of the participants were instructed to use their nondominant hand to eat. This disruption in the fluid execution of habitual eaters' consumption should not affect their judgments of the popcorn. Instead, the manipulation should hinder the automatic execution of the habitual response and bring behavior under intentional control—so that participants can be guided by their motivations and eat more fresh than stale popcorn. Thus, we tested whether participants with strong cinema-popcorn habits, when eating with their nondominant hand at the cinema, would be hindered in automatically repeating their past behavior and instead would become responsive to food freshness, consuming only popcorn they liked.

The study also assessed several potential alternative explanations for the predicted effects. To see whether the hand manipulation affected consumption by prompting people to attend more to the popcorn's freshness (and perhaps especially so for those with strong habits), we tested people's recall for specific details of the movie trailers. We reasoned that participants attending closely to the popcorn would, by definition, be attending less to the trailers and thus would recall fewer specific details. Also, based on prior work in

Downloaded from psp.sagepub.com at UNIV OF ILLINOIS URBANA on October 19, 2014

action identification theory (Vallacher & Wegner, 1989) and construal level theory (Trope & Liberman, 2010), we tested whether the hand manipulation encouraged people to construe popcorn consumption at a lower, more concrete level, thereby highlighting lower level, immediate outcomes such as taste. Finally, we assessed participants' perceived norms to eat popcorn and tested whether variation in normative beliefs could explain the effects of habit. Thus, Study 2 tested for changes in attention, construal level, and perceived norms as possible explanations for the predicted effects.

Method

Design and participants. The design of Study 2 was identical to Study 1 except that the context manipulation was replaced by a manipulation to eat with a particular hand. Thus, the design was a Hand Used to Eat (dominant vs. nondominant) × Food Freshness (fresh vs. stale) between-participants design. Eighty-nine participants (47 males) were paid $6 for completing the study.[3]

Procedure

Participants were recruited and participated just before the showing of a feature film at a campus cinema. Procedural details mirrored the cinema condition of Study 1, with the exception of the manipulation of the hand participants used to eat. For this manipulation, we designed a modified popcorn box with a vertically aligned handle on one side. Participants were instructed to slide one hand in-between the handle and the box and hold the box in that manner throughout the session. This instruction was embedded in several other methodological details and framed as necessary for experimental control. Testing sessions were randomly assigned such that, in half, participants were instructed to hold the box in their left (vs. right) hand.

In the follow-up survey, participants completed the Edinburgh Handedness Inventory (Oldfield, 1971). This enabled us to code participants according to whether they had eaten with their typical, dominant hand or their atypical, nondominant hand. Ambidextrous participants ($N = 4$) were coded as dominant hand eaters, but excluding this group did not alter the results reported below. At the study conclusion, participants were asked for an anonymous, honest estimate regarding the percentage of eating time in which they had actually used the instructed hand to eat. Estimates were made on an 11-point scale (*0% of the time* to *100% of the time*). Compliance with the hand manipulation was good. Ninety percent of the sample reported complying 100% of the time. Those who deviated did so an average of only 10% of the time. Excluding these participants or including compliance as a control variable did not alter the reported results.

Normative beliefs. To evaluate the extent to which habit performance depends on social norms, in the final survey participants rated on a 7-point scale the extent to which "other people important to them think that it's normal to eat popcorn at the cinema" (anchors *strongly disagree* to *strongly agree*). Because this item was not a close-to-significant predictor of consumption, it is not discussed further.

Attention to the trailers. To assess how much attention participants paid to the movie trailers, they answered nine difficult questions about the trailers (e.g., "What color did the main character in 'Whip It' dye her hair?"). The only close-to-significant effect in the analyses on factual recall was a trend for slightly worse recall among strong-habit participants, $B = –0.41$, $t(80) = 1.78$, $SE = 0.23$, $p = .07$. This pattern counters the possibility that strong-habit participants were not attending to the popcorn and were able to attend more closely to the movie trailers.

Level of construal of popcorn eating. Three questions assessed whether people construed the act of eating popcorn in the study at a higher, more abstract level versus a lower, more concrete level. Modeled after Vallacher and Wegner's (1989) research, each question involved choosing between a more concrete description of eating popcorn (i.e., chewing, holding a box, placing food in your mouth) and a more abstract one (i.e., part of the movie experience, sharing something with other people, a healthful snack). The sum of abstract choices (range = 0-3) served as the measure of construal level. Consistent with action identification theory and construal level theory, more habitual eaters preferred more abstract descriptions of popcorn consumption, $B = 0.14$, $t(81) = 2.51$, $SE = 0.07$, $p = .036$. However, the interaction between habit strength and hand used to eat did not significantly predict construal ($t > 1.2$). Thus, the predicted effects of the manipulation cannot be explained by changes in construal level.

Results and Discussion

The hypotheses were tested using a regression model with the following predictors: hand used to eat, popcorn freshness, habit strength to eat popcorn in theaters, and all two- and three-way interactions. Gender was a control variable in all analyses.

Reported attitudes and hunger. The model predicting participants' liking of the popcorn they received yielded only a main effect, reflecting that participants disliked the stale popcorn ($M = 3.43$, $SD = 1.59$) more than the fresh ($M = 4.35$, $SD = 1.59$), $B = 1.02$, $t(81) = 3.44$, $SE = 0.30$, $p = .001$. Importantly, this effect was not qualified by any interactions with context or habit strength.[4] As can be seen from the liking means in Table 1, no other differences emerged across conditions. Thus, mean liking did not vary with the hand used to eat, $t(85) = 0.78$, $SE = 0.33$, $p = .44$. Prestudy hunger levels also were identical among those eating with their dominant versus nondominant hand, $t(85) = 000$, $SE = 0.26$, $p = 1.00$.

Factors influencing performance of eating habits. The model predicting percentage of popcorn consumed yielded a main

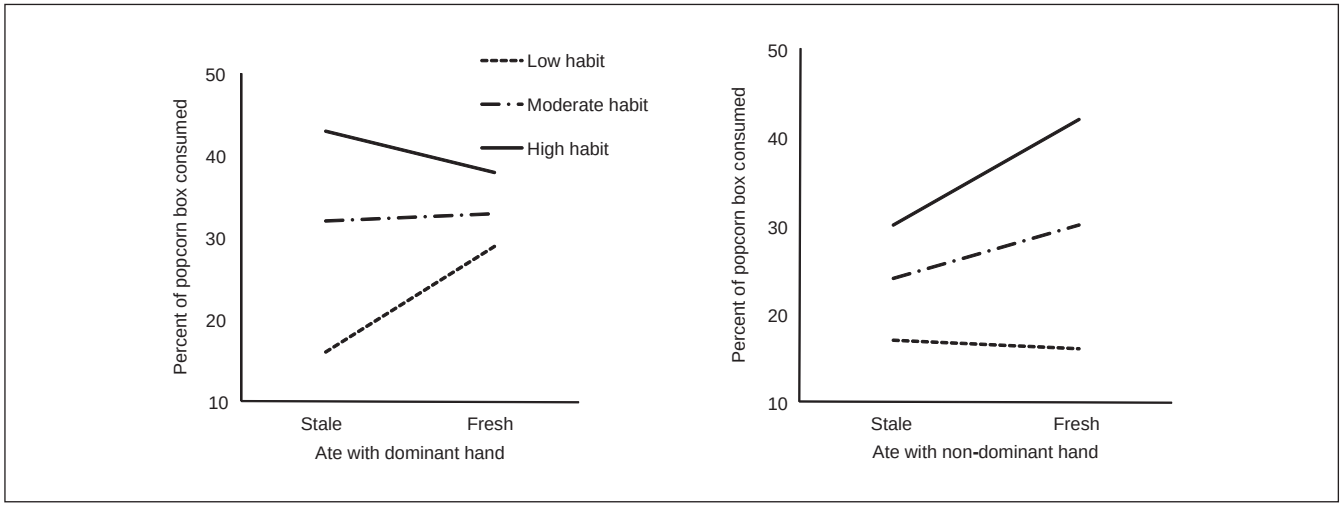

Figure 2. Percentage of popcorn eaten during 15 min of movie trailers in the cinema when participants were eating with their typical, dominant hand or atypical, nondominant hand (Study 2)
Simple slopes depict percent consumed of stale and fresh popcorn for those with strong (mean + 1 *SD*), moderate (mean), and weak (mean – 1 *SD*) habits for eating popcorn at cinemas.

effect of habit strength, $B = 6.74$, $t(81) = 2.55$, $SE = 2.64$, $p = .013$, and a marginal effect of hand used to eat, $B = 8.27$, $t(81) = 1.67$, $SE = 4.95$, $p = .094$. These main effects were qualified by the predicted three-way interaction between habit strength, hand used to eat, and freshness, $B = 8.52$, $t(81) = 2.22$, $SE = 3.84$, $p = .029$. To test whether strong habits were executed automatically— regardless of freshness— only when participants used their dominant hand, we calculated simple regression slopes between percent of popcorn consumed and freshness of the popcorn separately for participants with weak, moderate, and strong consumption habits as a function of the hand they used to eat (Cohen et al., 2003).

As predicted (see Figure 2), using the dominant versus nondominant hand to eat popcorn apparently enabled or disrupted habit cuing. That is, habitual eaters using their dominant hand automatically executed the response activated in the cinema context. The same amount of fresh and stale popcorn was eaten by participants with moderate habits, $B = –1.41$, $t(81) = 0.46$, $SE = 3.07$, $p = .647$, and strong habits, $B = 8.81$, $t(81) = 1.55$, $SE = 5.68$, $p = .13$. Only participants with weak habits ate significantly less stale than fresh popcorn when eating with the dominant hand, $B = –11.64$, $t(81) = 1.99$, $SE = 5.84$, $p = .053$.

Participants eating with their nondominant hand, in contrast, did not respond habitually to the cinema context and were influenced by popcorn freshness. Specifically, those with moderate habits ate significantly less stale than fresh popcorn, $B = –6.44$, $t(81) = 2.04$, $SE = 3.16$, $p = .048$, and those with strong habits ate marginally less, $B = –12.89$, $t(81) = 1.91$, $SE = 6.75$, $p = .063$. Unexpectedly, those with weak habits did not eat less stale than fresh popcorn when eating with their nondominant hand, $B = 0.02$, $t(81) = 0.01$, $SE = 2.00$, $p = .998$. However, inspection of the consumption rates for this group suggests a floor effect, such that eating with the nondominant hand was at such a low rate among these individuals that the stale popcorn could not induce further declines.

Habit performance did not depend on motives. As in Study1, we tested directly whether habit performance depended on participants' hunger and liking for popcorn. Although hungrier participants ate marginally more in general, $B = 2.72$, $t(79) = 1.76$, $SE = 1.55$, $p = .08$, the critical interaction between hunger and habit strength was not significant ($t < 1$), suggesting that habit effects did not depend on this motive. Even more importantly, after including hunger and the Hunger × Habit Strength interaction in the model, the predicted three-way interaction maintained between habit strength, context, and freshness, $B = 7.75$, $t(79) = 2.01$, $SE = 3.86$, $p = .048$.

In the analyses on liking as a moderator, this motivation yielded a main effect, with participants eating more popcorn if they liked it more, $B = 3.90$, $t(79) = 2.52$, $SE = 1.34$, $p = .014$. However, the interaction between liking and habit strength was not significant ($t < 1$), suggesting that the habit effects did not depend on this attitude. After adding these additional terms to the model, the critical three-way interaction between habit strength, context, and freshness dropped below significance, $B = 5.54$, $t(79) = 1.50$, $SE = 3.69$, $p = .13$. However, the low power to detect effects in this model may have contributed to this nonsignificant finding.

In general, just like Study 1, habitual cinema-popcorn eaters did not like the popcorn any more or less than nonhabitual eaters. Everyone disliked the stale popcorn and expressed neutral attitudes toward the fresh. It is also interesting that strong-habit participants expressed the same normative beliefs about eating popcorn in the cinema as weak-habit participants. Also, the slightly lower recall of the movie

Downloaded from psp.sagepub.com at UNIV OF ILLINOIS URBANA on October 19, 2014

trailers among strong-habit participants suggests that their attention was not unduly captured by these presentations, and thus they could attend to the quality of the popcorn as much as weak-habit participants. Finally, although strong-habit participants did favor more abstract descriptions of popcorn consumption, this tendency was not altered by the hand use manipulation, making changes in construal level an unlikely explanation for the results.

Despite the comparable subjective judgments of participants with strong and weak habits, striking differences emerged in their eating patterns. Strong-habit participants, when they could eat automatically with their dominant hand, repeated their past responses regardless of the palatability of the food. However, when strong-habit participants were forced to eat in an atypical way, their behavior was brought under intentional control, and—like the weak-habit participants in all conditions—they ate little of the stale popcorn.

General Discussion

Two field experiments tested the factors controlling a socially significant habit, eating behavior. In both experiments, participants' eating habits were resistant to changes in attitudes and goals. Strong habits persisted regardless of whether participants were hungry and whether the popcorn was fresh and palatable or stale and distasteful. Thus, when in the context associated with frequent past consumption, strong-habit participants rigidly carried out their past responses. Unlike the motivated types of automaticity studied most often in social psychology, habit responses were not sensitive to participants' current motivational states. Instead, strong-habit participants acted on habitual responses in memory to such an extent that they ate even food they disliked.

Habitual eating, although not influenced by motivations, was disrupted by factors that we anticipated would block the processes of habit automaticity. That is, participants in an environment not associated with past consumption (a meeting room) should not have the habitual response automatically brought to mind. Also, participants at the cinema eating in a novel way (with their nondominant hand) should not have been able to automatically carry out the response in mind. Our experiments thus directly manipulated the critical mechanisms that enable habit performance. When habit automaticity was apparently disrupted, participants' eating came under intentional control. That is, participants ate more when they were hungry and when they liked the popcorn—yielding greater consumption of fresh than stale popcorn. The findings thus echo prior research showing that people relying on their habits were less responsive to the outcomes of their behavior (Ji & Wood, 2007; Verplanken, Aarts, & van Knippenberg, 1997). By disrupting habitual eaters' automatic activation and execution of their past behavior, the present research reveals further that responsiveness to outcomes can be restored.

Importantly, the different eating patterns of strong- and weak-habit participants could not be explained by differences in the subjective evaluation of the popcorn. Habitual eaters recognized that the stale popcorn was not palatable, and they reported disliking it just as extremely as did nonhabitual eaters. It is striking, then, that these negative attitudes only curtailed habitual eaters' consumption when habit automaticity was disrupted. At the process level, the results do not appear to be due to changes in attention, social norms, or construal level across experimental conditions. Our check on recall of the details of the movie trailers in Study 2 revealed that the hand use manipulation did not change how much attention people paid to the popcorn, either as a main effect or through an interaction with habit strength. Also, all participants held similar norms to eat popcorn in the cinema. Finally, the hand use manipulation did not alter whether people thought about their popcorn consumption at a more abstract versus a more concrete level. Thus, it appears unlikely that the manipulation to disrupt habit automaticity worked through these alternative mechanisms.

The present study contributes to growing evidence that performance settings can serve as direct cues to habitual behavior. Habitual runners have been found to have strong cognitive associations between the location in which they typically trained and mental representations of running (Neal et al., 2011). Similarly, in behavior prediction studies, strong-habit participants tend to repeat responses independently of intentions when they are in familiar performance contexts (Ji & Wood, 2007). Based on this earlier research, we anticipated that the actual location of the theater might serve as a trigger to habit performance. Yet, the actual triggers might include a variety of aspects of the cinema setting and the evening show time. Because we had participants sit some distance from each other in the cinema, we doubt that movie companions were triggers for consumption in the present studies. Furthermore, because we used the same popcorn and the same bags in the cinema and meeting rooms, these features cannot have triggered habit performance. However, the exact nature of the triggering cues is a question for future research.

In general, our findings expand on work conducted by Wansink and colleagues in which the quantity of food people consume is influenced by simple manipulations of environmental cues such as plate and serving size (e.g., Sobal & Wansink, 2007; Wansink & Kim, 2005). Our results suggest that such environmental cues are likely to be most influential when people have developed habits to respond in particular ways to the cue. The current results also suggest a possible role for eating habits in Schachter's (1968) externality hypothesis, which stipulated that obese individuals are more driven by external cues and less by internal cues than are nonobese individuals (see also Wansink, Payne, & Chandon, 2007). Obesity has been linked to eating patterns such as nocturnal snacking that are repeated consistently at particular times of day (Berg et al., 2009). Thus, obese individuals may rely less than nonobese people on internal cues partly

Downloaded from psp.sagepub.com at UNIV OF ILLINOIS URBANA on October 19, 2014

because their eating behavior is more habitual, leading them to respond as cued by environments of past consumption.

Finally, our findings suggest ways to gain traction on the difficult problem of habit change (see Rothman, Sheeran, & Wood, 2009; Verplanken & Wood, 2006). Consistent with the idea that habits are a form of non-goal-dependent automaticity (see Bargh, 1994; Moors & De Houwer, 2006), habits may not be especially sensitive to alterations in motivational states but instead may best be disrupted by changes in triggering contexts. Habit change may thus require impeding habit activation or interrupting fluid habit execution. Although our findings suggest that both avenues are effective, it is not always possible for dieters to avoid or alter the environments in which they typically overeat (see Quinn, Pascoe, Wood, & Neal, 2010). More feasible, perhaps, is for dieters to actively disrupt the execution of the activated eating sequence by simple manipulations such as eating with the nondominant hand and, in so doing, bring their eating under their personal control.

Notes

1. In Study 1, 16 additional participants (7 in the cinema context, 9 in the meeting room context) were excluded from the analysis because they either declined the popcorn or did not eat any and thus were not exposed to the freshness manipulation.
2. To further test for possible effects of habit strength on liking, we created high- and low-habit groups via a median split of the habit variable. As with the continuous measure, strong-habit participants liked the fresh popcorn ($M = 3.66$, $SD = 0.77$) significantly more than the stale popcorn ($M = 2.70$, $SD = 1.11$), and weak-habit participants also liked the fresh popcorn ($M = 3.33$, $SD = 1.14$) more than the stale popcorn ($M = 2.83$, $SD = 1.05$). An ANOVA on this dichotomous measure of habit strength yielded only a main effect of freshness, $F(1, 146) = 18.58$, $p < .001$, and the Habit × Freshness interaction term was not significant ($F < 2$).
3. In Study 2, 15 additional participants (8 in the right-hand condition, 7 in the left-hand condition) were excluded because they either declined the popcorn box or did not eat any popcorn and thus were not exposed to the freshness manipulation.
4. As in Study 1, we used a median split of habit strength to explore potential differences in liking. Again, strong-habit participants liked the fresh popcorn ($M = 4.38$, $SD = 1.76$) significantly more than the stale popcorn ($M = 3.00$, $SD = 1.60$), and weak-habit participants also liked the fresh popcorn ($M = 4.25$, $SD = 1.12$) more than the stale popcorn ($M = 2.84$, $SD = 1.18$). An ANOVA on this dichotomous measure of habit strength yielded only a main effect of freshness, $F(1, 83) = 19.16$, $p < .001$, and the habit and Habit × Freshness interaction terms were not significant (Fs > 1).
